

ASM HANDBOOK®

VOLUME

1

Properties and
Selection: Irons
Steels and High
Performance
Alloys

Volume 1 Publication Information and Contributors

Properties and Selection: Irons, Steels, and High-Performance Alloys was published in 1990 as Volume 1 of the 10th Edition *Metals Handbook*. With the second printing (1993), the series title was changed to *ASM Handbook*. The Volume was prepared under the direction of the ASM International Handbook Committee.

Authors and Reviewers

- **LAMET** UFRGS

Foreword

For nearly 70 years the *Metals Handbook* has been one of the most widely read and respected sources of information on the subject of metals. Launched in 1923 as a single volume, it has remained a durable reference work, with each succeeding edition demonstrating a continuing upward trend in growth, in subject coverage, and in reader acceptance. As we enter the final decade of the 20th century, the ever-quicken pace of modern life has forced an increasing demand for timely and accurate technical information. Such a demand was the impetus for this, the 10th Edition of *Metals Handbook*.

Since the publication of Volume 1 of the 9th Edition in 1978, there have been significant technological advances in the field of metallurgy. The goal of the present volume is to document these advances as they pertain to the properties and selection of cast irons, steels, and superalloys. A companion volume on properties and selection of nonferrous alloys, special-purpose materials, and pure metals will be published this autumn. Projected volumes in the 10th Edition will present expanded coverage on processing and fabrication of metals; testing, inspection, and failure analysis; microstructural analysis and materials characterization; and corrosion and wear phenomena (the latter a subject area new to the Handbook series).

During the 12 years it took to complete the 17 volumes of the 9th Edition, the high standards for technical reliability and comprehensiveness for which *Metals Handbook* is internationally known were retained. Through the collective efforts of the ASM Handbook Committee, the editorial staff of the Handbook, and nearly 200 contributors from industry, research

organizations, government establishments, and educational institutions, Volume 1 of the 10th Edition continues this legacy of excellence.

ASM INTERNATIONAL

Preface

During the past decade, tremendous advances have taken place in the field of materials science. Rapid technological growth and development of composite materials, plastics, and ceramics combined with continued improvements in ferrous and nonferrous metals have made materials selection one of the most challenging endeavors for engineers. Yet the process of selection of materials has also evolved. No longer is a mere recitation of specifications, compositions, and properties adequate when dealing with this complex operation. Instead, information is needed that explains the correlation among the processing, structures, and properties of materials as well as their areas of use. It is the aim of this volume--the first in the new 10th Edition series of *Metals Handbook*--to present such data.

Like the technology it documents, the *Metals Handbook* is also evolving. To be truly effective and valid as a reference work, each Edition of the Handbook must have its own identity. To merely repeat information, or to simply make superficial cosmetic changes, would be self-defeating. As such, utmost care and thought were brought to the task of planning the 10th Edition by both the ASM Handbook Committee and the Editorial Staff.

To ensure that the 10th Edition continued the tradition of quality associated with the Handbook, it was agreed that it was necessary to:

- Determine which subjects (articles) not included in previous Handbooks needed to be added to the 10th Edition
- Determine which previously published articles needed only to be revised and/or expanded
- Determine which previously published articles needed to be completely rewritten
- Determine which areas needed to be de-emphasized
- Identify and eliminate obsolete data

The next step was to determine how the subject of properties selection should be addressed in the 10th Edition. Considering the information explosion that has taken place during the past 30 years, the single-volume approach used for Volume 1 of the 8th Edition (published in 1961) was not considered feasible. For the 9th Edition, three separate volumes on properties and selection were published from 1978 to 1980. This approach, however, was considered somewhat fragmented, particularly in regard to steels: carbon and low-alloy steels were covered in Volume 1, whereas tools steels, austenitic manganese steels, and stainless steels were described in Volume 3. After considering the various options, it was decided that the most logical and user-friendly approach would be to publish two comprehensive volumes on properties and selection. In the present volume, emphasis has been placed on cast irons, carbon and low-alloy steels, and high-performance alloys such as stainless steels and superalloys. A companion volume on properties and selection of nonferrous alloys and special-purpose materials will follow (see Table 1 for an abbreviated table of contents).

Table 1 Abbreviated table of contents for Volume 2, 10th Edition, Metals Handbook

Specific Metals and Alloys
Wrought Aluminum and Aluminum Alloys

Cast Aluminum Alloys
Aluminum-Lithium Alloys
Aluminum P/M Alloys
Wrought Copper and Copper Alloys
Cast Copper Alloys
Copper P/M Products
Nickel and Nickel Alloys
Beryllium-Copper and Beryllium-Nickel Alloys
Cobalt and Cobalt Alloys
Magnesium and Magnesium Alloys
Tin and Tin Alloys
Zinc and Zinc Alloys
Lead and Lead Alloys
Refractory Metals and Alloys
Wrought Titanium and Titanium Alloys
Cast Titanium Alloys
Titanium P/M Alloys
Zirconium and Hafnium
Uranium and Uranium Alloys
Beryllium

Precious Metals
Rare Earth Metals
Germanium and Germanium Compounds
Gallium and Gallium Compounds
Indium and Bismuth
Special-Purpose Materials
Soft Magnetic Materials
Permanent Magnet Materials
Metallic Glasses
Superconducting Materials
Electrical Resistance Alloys
Electric Contact Materials
Thermocouple Materials
Low Expansion Alloys
Shape-Memory Alloys
Materials For Sliding Bearings
Metal-Matrix Composite Materials
Ordered Intermetallics
Cemented Carbides
Cermets

Superabrasives and Ultrahard Tool Materials
Structural Ceramics
Pure Metals
Preparation and Characterization of Pure Metals
Properties of Pure Metals
Special Engineering Topics
Recycling of Nonferrous Alloys
Toxicity of Metals

Principal Sections

Volume 1 has been organized into seven major sections:

- Cast Irons
- Carbon and Low-Alloy Steels
- Hardenability of Carbon and Low-Alloy Steels
- Fabrication Characteristics of Carbon and Low-Alloy Steels
- Service Characteristics of Carbon and Low-Alloy Steels
- Specialty Steels and Heat-Resistant Alloys
- Special Engineering Topics

Of the 53 articles contained in these sections, 14 are new, 10 were completely rewritten, and the remaining articles have been substantially revised. A review of the content of the major sections is given below; highlighted are differences between the present volume and its 9th Edition predecessor. Table 2 summarizes the content of the principal sections.

Table 2 Summary of contents for Volume 1, 10th Edition, Metals Handbook

Section title	Number of articles	Pages	Figures ^(a)	Tables ^(b)	References
Cast Irons	6	104	155	81	108
Carbon and Low-Allow Steels	21	344	298	266	230
Hardenability of Carbon and Low-Alloy Steels	3	122	210	178	28
Fabrication Characteristics of Carbon and Low-Alloy Steels	4	44	56	10	85

Service Characteristics of Carbon and Low-Alloy Steels	6	140	219	22	567
Specialty Steels and Heat-Resistant Alloys	11	252	249	163	358
Special Engineering Topics	2	27	29	11	50
Totals	53	1033	1216	731	1426

(a) Total number of figure captions; some figures may include more than one illustration.

(b) Does not include unnumbered in-text tables or tables that are part of figures

Cast irons are described in six articles. The introductory article on "Classification and Basic Metallurgy of Cast Irons" was completely rewritten for the 10th Edition. The article on "Compacted Graphite Iron" is new to the Handbook. Both of these contributions were authored by D.M. Stefanescu (The University of Alabama), who served as Chairman of Volume 15, *Casting*, of the 9th Edition. The remaining four articles contain new information on materials (for example, austempered ductile iron) and testing (for example, dynamic tear testing).

Carbon and Low-Alloy Steels. Key additions to this section include articles that explain the relationships among processing (both melt and rolling processes), microstructures, and properties of steels. Of particular note is the article by G. Krauss (Colorado School of Mines) on pages 126 to 139 and the various articles on high-strength low-alloy steels. Other highlights include an extensive tabular compilation that cross-references SAE-AISI steels to their international counterparts (see the article "Classification and Designation of Steels") and an article on "Bearing Steels" that compares both case-hardened and through-hardened bearing materials.

Hardenability of Carbon and Low-Alloy Steels. Following articles that introduce H-steels and describe hardenability concepts, including test procedures to determine the hardening response of steels, a comprehensive collection of hardenability curves is presented. Both English and metric hardenability curves are provided for some 86 steels.

Fabrication Characteristics. Sheet formability, forgeability, machinability, and weldability are described next. The article on bulk formability, which emphasizes recent studies on HSLA forging steels, is new to the Handbook series. The material on weldability was completely rewritten and occupies nearly four times the space allotted in the 9th Edition.

Service Characteristics. The influence of various in-service environments on the properties of steels is one of the most widely studied subjects in metallurgy. Among the topics described in this section are elevated-temperature creep properties, low-temperature fracture toughness, fatigue properties, and impact toughness. A new article also describes the deleterious effect of neutron irradiation on alloy and stainless steels. Of critical importance to this section, however, is the definitive treatise on "Embrittlement of Steels" written by G.F. Vander Voort (Carpenter Technology Corporation). Featuring more than 75 graphs and 372 references, this 48-page article explores the causes and effects of both thermal and environmental degradation on a wide variety of steels. Compared with the 9th Edition on the same subject, this represents a nearly tenfold increase in coverage.

Specialty Steels and Heat-Resistant Alloys. Eleven articles on wrought, cast, and powder metallurgy materials for specialty and/or high-performance applications make up this section. Alloy development and selection criteria as related to corrosion-resistant and heat-resistant steels and superalloys are well documented. More than 100 pages are devoted to stainless steels, while three new articles have been written on superalloys—including one on newly developed directionally solidified and single-crystal nickel-base alloys used for aerospace engine applications.

Special Engineering Topics. The final section examines two subjects that are becoming increasingly important to the engineering community: (1) the availability and supply of strategic materials, such as chromium and cobalt, used in

stainless steel and superalloy production, and (2) the current efforts to recycle highly alloyed materials. Both of these subjects are new to the Handbook series. A second article on recycling of nonferrous alloys will be published in Volume 2 of the 10th Edition.

Acknowledgments

Successful completion of this Handbook required the cooperation and talents of literally hundreds of professional men and women. In terms of the book's technical content, we are indebted to the authors, reviewers, and miscellaneous contributors—some 200 strong—upon whose collective experience and knowledge rests the accuracy and authority of the volume. Thanks are also due to the ASM Handbook Committee and its capable Chairman, Dennis D. Huffman (The Timken Company). The ideas and suggestions provided by members of the committee proved invaluable during the two years of planning required for the 10th edition. Lastly, we would like to acknowledge the efforts of those companies who have worked closely with ASM's editorial and production staff on this and many other Handbook volumes. Our thanks go to Byrd Data Imaging for their tireless efforts in maintaining a demanding typesetting schedule, to Rand McNally & company for the care and quality brought to printing the Handbook, and to Precision Graphics, Don O. Tech, Accurate Art, and HaDel Studio for their attention to detail during preparation of Handbook artwork. Their combined efforts have resulted in a significant and lasting contribution to the metals industry.

The Editors

General Information

Officers and Trustees of ASM INTERNATIONAL (1990-1991)

- **Klaus M. Zwilsky** President and Trustee National Materials Advisory Board National Academy of Sciences
- **Stephen M. Copley** Vice President and Trustee Illinois Institute of Technology

- **D.J. Wright** (1964-1965) (Member, 1959-1967)

Staff

ASM International staff who contributed to the development of the Volume included Robert L. Stedfeld, Director of Reference Publications, Joseph R. Davis, Manager of Handbook Development; Kathleen M. Mills, Manager of Book Production; Steven R. Lampman, Technical Editor; Theodore B. Zorc, Technical Editor; Heather F. Lampman, Editorial Supervisor; George M. Crankovic, Editorial Coordinator; Alice W. Ronke, Assistant Editor; Scott D. Henry, Assistant Editor; Janice L. Daquila, Assistant Editor; Janet Jakel, Word Processing Specialist; Karen Lynn O'Keefe, Word Processing Specialist. Editorial assistance was provided by Lois A. Abel, Robert T. Kiepora, Penelope Thomas, and Nikki D. Wheaton.

Conversion to Electronic Files

ASM Handbook, Volume 1, *Properties and Selection: Irons, Steels, and High-Performance Alloys* was converted to electronic files in 1997. The conversion was based on the Fourth Printing (1995). No substantive changes were made to the content of the Volume, but some minor corrections and clarifications were made as needed.

ASM International staff who contributed to the conversion of the Volume included Sally Fahrenholz-Mann, Bonnie Sanders, Scott Henry, Grace Davidson, Randall Boring, Robert Braddock, and Kathleen Dragolich. The electronic version was prepared under the direction of William W. Scott, Jr., Technical Director, and Michael J. DeHaemer, Managing Director.

Classification and Basic Metallurgy of Cast Iron

Doru M. Stefanescu, The University of Alabama

Classification

Historically, the first classification of cast iron was based on its fracture. Two types of iron were initially recognized:

- *White iron*: Exhibits a white, crystalline fracture surface because fracture occurs along the iron carbide plates; it is the result of metastable solidification (Fe_3C eutectic)

- *Gray iron*: Exhibits a gray fracture surface because fracture occurs along the graphite plates (flakes); it is the result of stable solidification (Gr eutectic)

With the advent of metallography, and as the body of knowledge pertinent to cast iron increased, other classifications based on microstructural features became possible:

- *Graphite shape*: Lamellar (flake) graphite (FG), spheroidal (nodular) graphite (SG), compacted (vermicular) graphite (CG), and temper graphite (TG); temper graphite results from a solid-state reaction (malleabilization)
- *Matrix*: Ferritic, pearlitic, austenitic, martensitic, bainitic (austempered)

This classification is seldom used by the floor foundryman. The most widely used terminology is the commercial one. A first division can be made in two categories:

- *Common cast irons*: For general-purpose applications, they are unalloyed or low alloy
- *Special cast irons*: For special applications, generally high alloy

The correspondence between commercial and microstructural classification, as well as the final processing stage in obtaining common cast irons, is given in Table 1. A classification of cast irons by their commercial names and structure is also given in the article "Classification of Ferrous Casting Alloys" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Table 1 Classification of cast iron by commercial designation, microstructure, and fracture

Commercial designation	Carbon-rich phase	Matrix ^(a)	Fracture	Final structure after
Gray iron	Lamellar graphite	P	Gray	Solidification
Ductile iron	Spheroidal graphite	F, P, A	Silver-gray	Solidification or heat treatment
Compacted graphite iron	Compacted vermicular graphite	F, P	Gray	Solidification
White iron	Fe ₃ C	P, M	White	Solidification and heat treatment^(b)
Mottled iron	Lamellar Gr + Fe ₃ C	P	Mottled	Solidification
Malleable iron	Temper graphite	F, P	Silver-gray	Heat treatment
Austempered ductile iron	Spheroidal graphite	At	Silver-gray	Heat treatment

(a) F, ferrite; P, pearlite; A, austenite; M, martensite; At, austempered (bainite).

(b) White irons are not usually heat treated, except for stress relief and to continue austenite transformation.

Special cast irons differ from the common cast irons mainly in the higher content of alloying elements (>3%), which promote microstructures having special properties for elevated-temperature applications, corrosion resistance, and wear resistance. A classification of the main types of special cast irons is shown in Fig. 2.

Principles of the Metallurgy of Cast Iron

The goal of the metallurgist is to design a process that will produce a structure that will yield the expected mechanical properties. This requires knowledge of the structure-properties correlation for the particular alloy under consideration as well as of the factors affecting the structure. When discussing the metallurgy of cast iron, the main factors of influence on the structure that one needs to address are:

- Chemical composition
- Cooling rate
- Liquid treatment
- Heat treatment

In addition, the following aspects of combined carbon in cast irons should also be considered:

- In the original cooling or through subsequent heat treatment, a matrix can be internally decarburized or carburized by depositing graphite on existing sites or by dissolving carbon from them
- Depending on the silicon content and the cooling rate, the pearlite in iron can vary in carbon content.

This is a ternary system, and the carbon content of pearlite can be as low as 0.50% with 2.5% Si

- The conventionally measured hardness of graphitic irons is influenced by the graphite, especially in gray iron. Martensite microhardness may be as high as 66 HRC, but measures as low as 54 HRC conventionally in gray iron (58 HRC in ductile)
- The critical temperature of iron is influenced (raised) by silicon content, not carbon content

The following sections in this article discuss some of the basic principles of cast iron metallurgy. More detailed descriptions of the metallurgy of cast irons are available in separate articles in this Volume describing certain types of cast irons. The Section "Ferrous Casting Alloys" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*, also contains more detailed descriptions on the metallurgy of cast irons.

Gray Iron (Flake Graphite Iron)

The **composition** of gray iron must be selected in such a way as to satisfy three basic structural requirements:

- The required graphite shape and distribution
- The carbide-free (chill-free) structure
- The required matrix

For common cast iron, the main elements of the chemical composition are carbon and silicon. Figure 3 shows the range of carbon and silicon for common cast irons as compared with steel. It is apparent that irons have carbon in excess of the maximum solubility of carbon in austenite, which is shown by the lower dashed line. A high carbon content increases the amount of graphite or Fe_3C . High carbon and silicon contents increase the graphitization potential of the iron as well as its castability.

Fig. 3 Carbon and silicon composition ranges of common cast irons and steel. Source: Ref 2

The combined influence of carbon and silicon on the structure is usually taken into account by the carbon equivalent (CE):

$$\begin{aligned} \text{CE} = & \% \text{ C} + 0.3(\% \text{ Si}) \\ & + 0.33(\% \text{ P}) - 0.027(\% \text{ Mn}) + 0.4(\% \text{ S}) \end{aligned}$$

(Eq 1)

Additional information on carbon equivalent is available in the article "Thermodynamic Properties of Iron-Base Alloys" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. Although increasing the carbon and silicon contents improves the graphitization potential and therefore decreases the chilling tendency, the strength is adversely affected (Fig. 4). This is due to ferrite promotion and the coarsening of pearlite.

Fig. 4 General influence of carbon equivalent on the tensile strength of gray iron. Source: Ref 2

The manganese content varies as a function of the desired matrix. Typically, it can be as low as 0.1% for ferritic irons and as high as 1.2% for pearlitic irons, because manganese is a strong pearlite promoter.

From the minor elements, phosphorus and sulfur are the most common and are always present in the composition. They can be as high as 0.15% for low-quality iron and are considerably less for high-quality iron, such as ductile iron or compacted graphite iron. The effect of sulfur must be balanced by the effect of manganese. Without manganese in the iron, undesired iron sulfide (FeS) will form at grain boundaries. If the sulfur content is balanced by manganese, manganese sulfide (MnS) will form, which is harmless because it is distributed within the grains. The optimum ratio between manganese and sulfur for an FeS-free structure and maximum amount of ferrite is:

$$\% \text{ Mn} = 1.7(\% \text{ S}) + 0.15$$

(Eq 2)

Other minor elements, such as aluminum, antimony, arsenic, bismuth, lead, magnesium, cerium, and calcium, can significantly alter both the graphite morphology and the microstructure of the matrix.

The range of composition for typical unalloyed common cast irons is given in Table 2. The typical composition range for low- and high-grade unalloyed gray iron (flake graphite iron) cast in sand molds is given in Table 3.

Table 2 Range of compositions for typical unalloyed common cast irons

Type of iron	Composition, %				
	C	Si	Mn	P	S

Gray (FG)	2.5-4.0	1.0-3.0	0.2-1.0	0.002-1.0	0.02-0.25
Compacted graphite (CG)	2.5-4.0	1.0-3.0	0.2-1.0	0.01-0.1	0.01-0.03
Ductile (SG)	3.0-4.0	1.8-2.8	0.1-1.0	0.01-0.1	0.01-0.03
White	1.8-3.6	0.5-1.9	0.25-0.8	0.06-0.2	0.06-0.2
Malleable (TG)	2.2-2.9	0.9-1.9	0.15-1.2	0.02-0.2	0.02-0.2

Table 3 Compositions of unalloyed gray irons

ASTM A 48 class	Carbon equivalent	Composition, %				
		C	Si	Mn	P	S
20B	4.5	3.1-3.4	2.5-2.8	0.5-0.7	0.9	0.15

Both major and minor elements have a direct influence on the morphology of flake graphite. The typical graphite shapes for flake graphite are shown in Fig. 5. Type A graphite is found in inoculated irons cooled with moderate rates. In general, it is associated with the best mechanical properties, and cast irons with this type of graphite exhibit moderate undercooling during solidification (Fig. 6). Type B graphite is found in irons of near-eutectic composition, solidifying on a limited number of nuclei. Large eutectic cell size and low undercoolings are common in cast irons exhibiting this type of graphite. Type C graphite occurs in hypereutectic irons as a result of solidification with minimum undercooling. Type D graphite is found in hypoeutectic or eutectic irons solidified at rather high cooling rates, while type E graphite is characteristic for strongly hypoeutectic irons. Types D and E are both associated with high undercoolings during solidification. Not only graphite shape but also graphite size is important, because it is directly related to strength (Fig. 7).

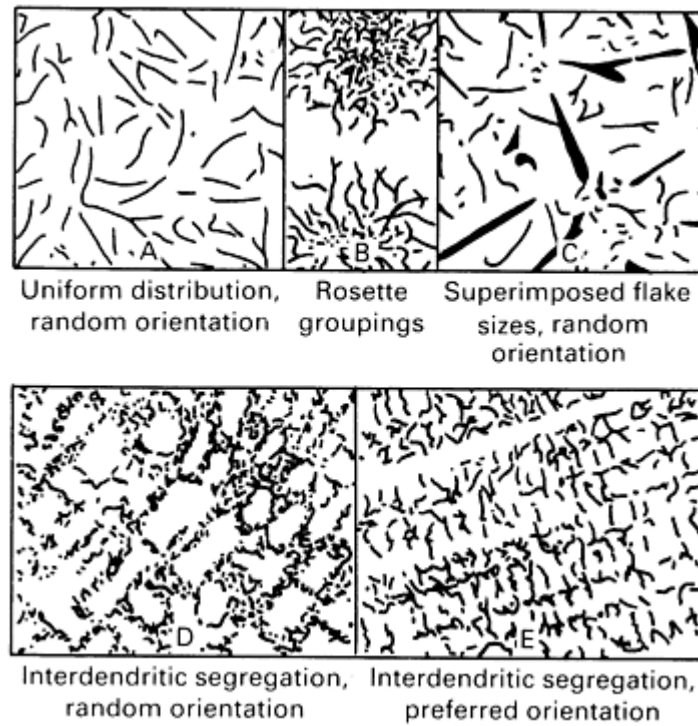

Fig. 5 Typical flake graphite shapes specified in ASTM A 247. A, uniform distribution, random orientation; B, rosette groupings; C, kish graphite (superimposed flake sizes, random orientation); D, interdendritic segregation with random orientation; E, interdendritic segregation with preferred orientation

Fig. 6 Characteristic cooling curves associated with different flake graphite shapes. T_E , equilibrium eutectic temperature

Fig. 7 Effect of maximum graphite flake length on the tensile strength of gray iron. Source: Ref 3

Alloying elements can be added in common cast iron to enhance some mechanical properties. They influence both the graphitization potential and the structure and properties of the matrix. The main elements are listed below in terms of their graphitization potential:

High positive graphitization potential (decreasing positive potential from top to bottom)
Carbon
Tin
Phosphorus
Silicon
Aluminum
Copper
Nickel
Neutral
Iron

High negative graphitization potential (increasing negative potential from top to bottom)
Manganese
Chromium
Molybdenum
Vanadium

This classification is based on the thermodynamic analysis of the influence of a third element on carbon solubility in the Fe-C-X system, where X is a third element (see the section "Influence of a Third Element on Carbon Solubility in the Fe-C-X System" in the article "Thermodynamic Properties of Iron-Base Alloys" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. Although listed as a graphitizer (which may be true thermodynamically), phosphorus also acts as a matrix hardener. Above its solubility level (probably about 0.08%), phosphorus forms a very hard ternary eutectic. The above classification should also include sulfur as a carbide former, although manganese and sulfur can combine and neutralize each other. The resultant manganese sulfide also acts as nuclei for flake graphite. In industrial processes, nucleation phenomena may sometimes override solubility considerations.

In general, alloying elements can be classified into three categories. Each is discussed below.

Silicon and aluminum increase the graphitization potential for both the eutectic and eutectoid transformations and increase the number of graphite particles. They form solid solutions in the matrix. Because they increase the ferrite/pearlite ratio, they lower strength and hardness.

Nickel, copper, and tin increase the graphitization potential during the eutectic transformation, but decrease it during the eutectoid transformation, thus raising the pearlite/ferrite ratio. This second effect is due to the retardation of carbon diffusion. These elements form solid solution in the matrix. Because they increase the amount of pearlite, they raise strength and hardness.

Chromium, molybdenum, tungsten, and vanadium decrease the graphitization potential at both stages. Thus, they increase the amount of carbides and pearlite. They concentrate in principal in the carbides, forming (FeX)_nC-type carbides, but also alloy the α Fe solid solution. As long as carbide formation does not occur, these elements increase strength and hardness. Above a certain level, any of these elements will determine the solidification of a structure with both Gr and Fe₃C (mottled structure), which will have lower strength but higher hardness.

In alloyed gray iron, the typical ranges for the elements discussed above are as follows:

Element	Composition, %
Chromium	0.2-0.6
Molybdenum	0.2-1
Vanadium	0.1-0.2

Nickel	0.6-1
Copper	0.5-1.5
Tin	0.04-0.08

The influence of composition and cooling rate on tensile strength can be estimated using (Ref 3):

$$\begin{aligned}
 \text{TS} = & 162.37 + 16.61/D - 21.78(\% \text{ C}) \\
 & -61.29(\% \text{ Si}) - 10.59 (\% \text{ Mn} - 1.7\% \text{ S}) \\
 & + 13.80(\% \text{ Cr}) + 2.05(\% \text{ Ni}) + 30.66(\% \text{ Cu}) \\
 & + 39.75(\% \text{ Mo}) + 14.16 (\% \text{ Si})^2 \\
 & -26.25(\% \text{ Cu})^2 - 23.83 (\% \text{ Mo})^2
 \end{aligned}
 \tag{Eq 3}$$

where D is the bar diameter (in inches). Equation 3 is valid for bar diameters of 20 to 50 mm (0.78 to 2 in.) and compositions within the following ranges:

Element	Composition, %
Carbon	3.04-3.29
Chromium	0.1-0.55
Molybdenum	0.03-0.78
Silicon	1.6-2.46
Nickel	0.07-1.62
Sulfur	0.089-0.106
Manganese	0.39-0.98
Copper	0.07-0.85

The cooling rate, like the chemical composition, can significantly influence the as-cast structure and therefore the mechanical properties. The cooling rate of a casting is primarily a function of its section size. The dependence of structure and properties on section size is termed section sensitivity. Increasing the cooling rate will:

- Refine both graphite size and matrix structure; this will result in increased strength and hardness

- Increase the chilling tendency; this may result in higher hardness, but will decrease the strength

Consequently, composition must be tailored in such a way as to provide the correct graphitization potential for a given cooling rate. For a given chemical composition and as the section thickness increases, the graphite becomes coarser, and the pearlite/ferrite ratio decreases, which results in lower strength and hardness (Fig. 8). Higher carbon equivalent has similar effects.

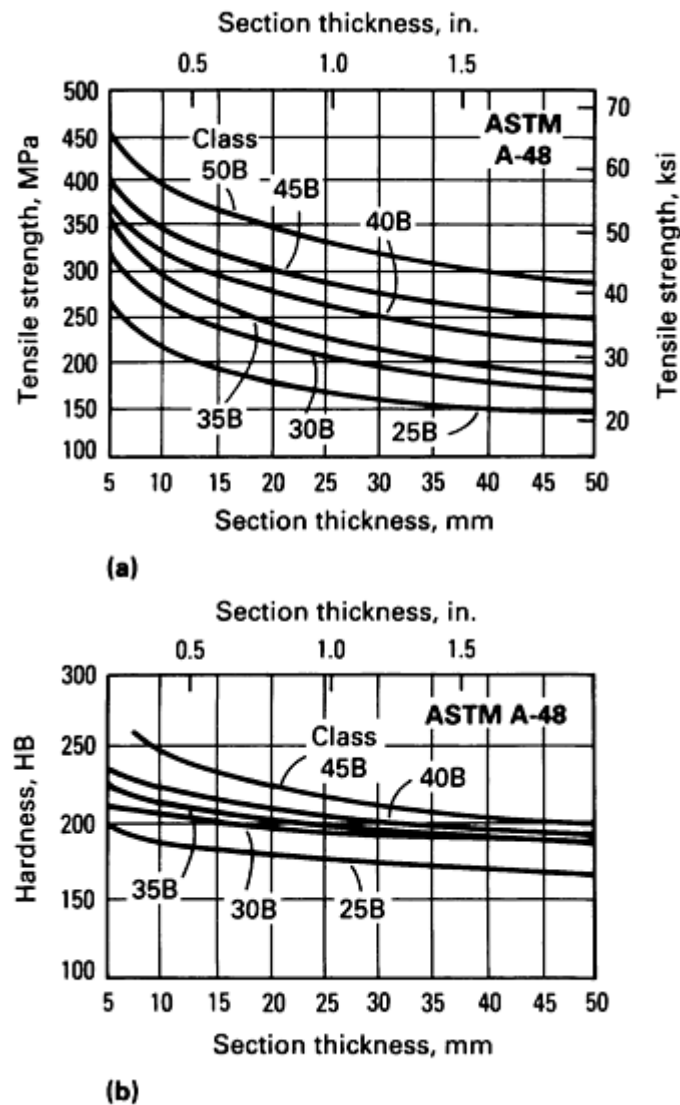

Fig. 8 Influence of section thickness of the casting on tensile strength (a) and hardness (b) for a series of gray irons classified by their strength as-cast in 30 mm (1.2 in.) diam bars. Source: Ref 2

The liquid treatment of cast iron is of paramount importance in the processing of this alloy because it can dramatically change the nucleation and growth conditions during solidification. As a result, graphite morphology, and therefore properties, can be significantly affected. In gray iron practice, the liquid treatment used is termed inoculation and consists of minute additions of minor elements before pouring. Typically, ferrosilicon with additions of aluminum and calcium, or proprietary alloys are used as inoculants. The main effects of inoculation are:

- An increased graphitization potential because of decreased undercooling during solidification; as a result of this, the chilling tendency is diminished, and graphite shape changes from type D or E to type A

- A finer structure, that is, higher number of eutectic cells, with a subsequent increase in strength

As shown in Fig. 9, inoculation improves tensile strength. This influence is more pronounced for low-CE cast irons.

Fig. 9 Influence of inoculation on tensile strength as a function of carbon equivalent for 30 mm (1.2 in.) diam bars. Source: Ref 2

Heat treatment can considerably alter the matrix structure, although graphite shape and size remain basically unaffected. A rather low proportion of the total gray iron produced is heat treated. Common heat treatment may consist of stress relieving or of annealing to decrease hardness.

Ductile Iron (Spheroidal Graphite Iron)

Composition. The main effects of chemical composition are similar to those described for gray iron, with quantitative differences in the extent of these effects and qualitative differences in the influence on graphite morphology. The carbon equivalent has only a mild influence on the properties and structure of ductile iron, because it affects graphite shape considerably less than in the case of gray iron. Nevertheless, to prevent excessive shrinkage, high chilling tendency, graphite flotation, or a high impact transition temperature, optimum amounts of carbon and silicon must be selected. Figure 10 shows the basic guidelines for the selection of appropriate compositions.

Fig. 10 Typical range for carbon and silicon contents in good-quality ductile iron. Source: Ref 2

As mentioned previously, minor elements can significantly alter the structure in terms of graphite morphology, chilling tendency, and matrix structure. Minor elements can promote the spheroidization of graphite or can have an adverse effect on graphite shape. The minor elements that adversely affect graphite shape are said to degenerate graphite shape. A variety of graphite shapes can occur, as illustrated in Fig. 11. Graphite shape is the single most important factor affecting the mechanical properties of cast iron, as shown in Fig. 12.

Fig. 12 Influence of graphite morphology on the stress-strain curve of several cast irons

The generic influence of various elements on graphite shape is given in Table 4. The elements in the first group--the spheroidizing elements--can change graphite shape from flake through compacted to spheroidal. This is illustrated in Fig. 13 for magnesium. The most widely used element for the production of spheroidal graphite is magnesium. The amount of residual magnesium, Mg_{resid} , required to produce spheroidal graphite is generally 0.03 to 0.05%. The precise level depends on the cooling rate. A higher cooling rate requires less magnesium. The amount of magnesium to be added in the iron is a function of the initial sulfur level, S_{in} , and the recovery of magnesium, η , in the particular process used:

$$Mg_{added} = \frac{0.75Si + Mg_{resid}}{h} \quad (\text{Eq 4})$$

Table 4 Influence of minor elements on graphite shape

Element category	Element
Spheroidizer	Magnesium, calcium, rare earths (cerium, lanthanum, etc.), yttrium
Neutral	Iron, carbon, alloying, elements
Antispheroidizer (degenerate shape)	Aluminum, arsenic, bismuth, tellurium, titanium, lead, sulfur, antimony

Fig. 13 Influence of residual magnesium on graphite shape

A residual magnesium level that is too low results in insufficient nodularity (that is, a low ratio between the spheroidal graphite and the total amount of graphite in the structure). This in turn results in a deterioration of the mechanical properties of the iron, as illustrated in Fig. 14. If the magnesium content is too high, carbides are promoted.

(a)

(b)

Fig. 14 Influence of residual magnesium (a) and nodularity (b) on some mechanical properties of ductile iron. Sources: Ref 4, 5

The presence of antispheroidizing (deleterious) minor elements may result in graphite shape deterioration, up to complete graphite degeneration. Therefore, upper limits are set on the amount of deleterious elements to be accepted in the composition of cast iron. Typical limits are given below (Ref 6):

Element	Composition, %
Aluminum	0.1
Arsenic	0.02

Bismuth	0.002
Cadmium	0.01
Lead	0.002
Antimony	0.002
Selenium	0.03
Tellurium	0.02
Titanium	0.1
Zirconium	0.1

These values can be influenced by the combination of various elements and by the presence of rare earths in the composition. Furthermore, some of these elements can be deliberately added during liquid processing in order to increase nodule count.

Alloying elements have in principle the same influence on structure and properties as for gray iron. Because a better graphite morphology allows more efficient use of the mechanical properties of the matrix, alloying is more common in ductile iron than in gray iron.

Cooling Rate. When changing the cooling rate, effects similar to those discussed for gray iron also occur in ductile iron, but the section sensitivity of ductile iron is lower. This is because spheroidal graphite is less affected by cooling rate than flake graphite.

The liquid treatment of ductile iron is more complex than that of gray iron. The two stages for the liquid treatment of ductile iron are:

- Modification, which consists of magnesium or magnesium alloy treatment of the melt, with the purpose of changing graphite shape from flake to spheroidal
- Inoculation (normally, postinoculation, that is, after the magnesium treatment) to increase the nodule count. Increasing the nodule count is an important goal, because a higher nodule count is associated with less chilling tendency (Fig. 15) and a higher as-cast ferrite/pearlite ratio

Fig. 15 Influence of the amount of 75% ferrosilicon added as a postinoculant on the nodule count and chill depth of 3 mm (0.12 in.) plates. Source: Ref 7

Heat treatment is extensively used in the processing of ductile iron because better advantage can be taken of the matrix structure than for gray iron. The heat treatments usually applied are as follows:

- Stress relieving
- Annealing to produce a ferritic matrix
- Normalizing to produce a pearlitic matrix
- Hardening to produce tempering structures
- Austempering to produce a ferritic bainite

The advantage of austempering is that it results in ductile irons with twice the tensile strength for the same toughness. A comparison between some mechanical properties of austempered ductile iron and standard ductile iron is shown in Fig. 16.

Fig. 16 Properties of some standard and austempered ductile irons. Source: Ref 8

Compacted Graphite Irons

Compacted graphite irons have a graphite shape intermediate between spheroidal and flake. Typically, compacted graphite looks like type IV graphite (Fig. 11). Consequently, most of the properties of CG irons lie in between those of gray and ductile iron.

The chemical composition effects are similar to those described for ductile iron. Carbon equivalent influences strength less obviously than for the case of gray iron, but more than for ductile iron, as shown in Fig. 17. The graphite shape is controlled, as in the case of ductile iron, through the content of minor elements. When the goal is to produce compacted graphite, it is easier from the standpoint of controlling the structure to combine spheroidizing (magnesium, calcium, and/or rare earths) and antispheroidizing (titanium and/or aluminum) elements. Additional information is available in the article "Compacted Graphite Irons" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Fig. 17 Effect of carbon equivalent on the tensile strength of flake, compacted, and spheroidal graphite irons cast in 30 mm (1.2 in.) diam bars. Source: Ref 9

The **cooling rate** affects properties less for gray iron but more for ductile iron (Fig. 18). In other words, CG iron is less section sensitive than gray iron. However, high cooling rates are to be avoided because of the high propensity of CG iron for chilling and high nodule count in thin sections.

Fig. 18 Influence of section thickness on the tensile strength of CG irons. Source: Ref 10

Liquid treatment can have two stages, as for ductile iron. Modification can be achieved with magnesium, Mg + Ti, Ce + Ca, and so on. Inoculation must be kept at a low level to avoid excessive nodularity.

Heat treatment is not common for CG irons.

Malleable Irons

Malleable cast irons differ from the types of irons previously discussed in that they have an initial as-cast white structure, that is, a structure consisting of iron carbides in a pearlitic matrix. This white structure is then heat treated (annealing at 800 to 970 °C, or 1470 to 1780 °F), which results in the decomposition of Fe_3C and the formation of temper graphite. The basic solid state reaction is:

The final structure consists of graphite and pearlite, pearlite and ferrite, or ferrite. The structure of the matrix is a function of the cooling rate after annealing. Most of the malleable iron is produced by this technique and is called blackheart malleable iron. Some malleable iron is produced in Europe by decarburization of the white as-cast iron, and it is called whiteheart malleable iron.

The composition of malleable irons must be selected in such a way as to produce a white as-cast structure and to allow for fast annealing times. Some typical compositions are given in Table 2. Although higher carbon and silicon reduce the heat treatment time, they must be limited to ensure a graphite-free structure upon solidification. Both tensile strength and elongation decrease with higher carbon equivalent. Nevertheless, it is not enough to control the carbon equivalent. The annealing time depends on the number of graphite nuclei available for graphitization, which in turn depends on, among other factors, the C/Si ratio. As shown in Fig. 19, a lower C/Si ratio (that is, a higher silicon content for a constant carbon equivalent) results in a higher temper graphite count. This in turn translates into shorter annealing times.

Fig. 19 Influence of C/Si ratio on the number of temper graphite clusters at constant carbon equivalent. Source: Ref 10

Manganese content and the Mn/S ratio must be closely controlled. In general, a lower manganese content is used when ferritic rather than pearlitic structures are desired. The correct Mn/S ratio can be calculated with Eq 2. Equation 2 is plotted in Fig. 20. Under the line described by Eq 2, all sulfur is stoichiometrically tied to manganese as MnS . The excess manganese is dissolved in the ferrite. In the range delimited by the lines given by Eq 2 and the line $\text{Mn/S} = 1$, a mixed sulfide, $(\text{Mn,Fe})\text{S}$, is formed. For Mn/S ratios smaller than 1, pure FeS is also formed. It is assumed that the degree of compacting of temper graphite depends on the type of sulfides occurring in the iron (Ref 11). When FeS is predominant, very compacted, nodular temper graphite forms, but some undissolved Fe_3C may persist in the structure, resulting in lower elongations. When MnS is predominant, although the graphite is less compacted, elongation is higher because of the completely Fe_3C -free structure.

Fig. 20 Influence of the Mn/S ratio on the shape of temper graphite. Bracketed elements are dissolved in the matrix.

The Mn/S ratio also influences the number of temper graphite particles. From this standpoint, the optimum Mn/S ratio is about 2 to 4 (Fig. 21).

Fig. 21 Influence of the Mn/S ratio on the number of temper graphite clusters after annealing. A, low-temperature holding for 12 h at 350 °C (660 °F); B, no low-temperature holding

Alloying elements can be used in some grades of pearlitic malleable irons. The manganese content can be increased to 1.2%, or copper, nickel, and/or molybdenum can be added. Chromium must be avoided because it produces stable carbides, which are difficult to decompose during annealing.

Cooling Rate. Like all other irons, malleable irons are sensitive to cooling rate. Nevertheless, because the final structure is the result of a solid-state reaction, they are the least section sensitive irons. Typical correlations between tensile strength, elongation, and section thickness are shown in Fig. 22.

Fig. 22 Influence of bar diameter on the tensile strength (a) and elongation (b) of blackheart malleable iron. Source: Ref 13

The liquid treatment of malleable iron increases the number of nuclei available for the solid-state graphitization reaction. This can be achieved in two different ways, as follows:

- By adding elements that increase undercooling during solidification. Typical elements in this category are magnesium, cerium, bismuth, and tellurium. Higher undercooling results in finer structure, which in turn means more γ -Fe₃C interface. Because graphite nucleates at the γ -Fe₃C interface, this means more nucleation sites for graphite. Higher undercooling during solidification also prevents the formation of unwanted eutectic graphite
- By adding nitrite-forming elements to the melt. Typical elements in this category are aluminum, boron, titanium, and zirconium

The heat treatment of malleable iron determines the final structure of this iron. It has two basic stages. In the first stage, the iron carbide is decomposed in austenite and graphite (Eq 5). In the second stage, the austenite is transformed into pearlite, ferrite, or a mixture of the two. Although there are some compositional differences between ferritic and pearlitic irons, the main difference is in the heat treatment cycle. When ferritic structures are to be produced, cooling rates in the range of 3 to 10 °C/h (5 to 18 °F/h) are required through the eutectoid transformation in the second stage. This is necessary to allow for a complete austenite-to-ferrite reaction. A typical annealing cycle for ferritic malleable iron is shown in Fig. 23. When pearlitic irons are to be produced, different schemes can be used, as shown in Fig. 24. The goal of the treatment is to achieve a eutectoid transformation according to the austenite-to-pearlite reaction. In some limited cases, quenching-tempering treatments are used for malleable irons.

Fig. 23 Heat treatment cycle for ferritic blackheart malleable iron. Source: Ref 1

Fig. 24 Heat treatment cycles for pearlitic blackheart malleable irons

Special Cast Irons

Special cast irons, as previously discussed, are alloy irons that take advantage of the radical changes in structure produced by rather large amounts of alloying elements. Abrasion resistance can be improved by increasing hardness, which in turn can be achieved by either increasing the amount of carbides and their hardness or by producing a martensitic structure. The least expensive material is white iron with a pearlitic matrix. Additions of 3 to 5% Ni and 1.5 to 2.5% Cr result in irons with $(\text{FeCr})_3\text{C}$ carbides and an as-cast martensitic matrix. Additions of 11 to 35% Cr produce $(\text{CrFe})_7\text{C}_3$ carbides, which are harder than the iron carbides. Additions of 4 to 16% Mn will result in a structure consisting of $(\text{FeMn})_3\text{C}$, martensite, and work-hardenable austenite.

Heat resistance depends on the stability of the microstructure. Irons used for these applications may have a ferritic structure with graphite (5% Si), a ferritic structure with stable carbides (11 to 28% Cr), or a stable austenitic structure with either spheroidal or flake graphite (18% Ni, 5% Si). For corrosion resistance, irons with high chromium (up to 28%), nickel (up to 18%), and silicon (up to 15%) are used.

Gray Iron

Revised by Charles V. White, GMI Engineering and Management Institute

Introduction

CAST IRONS are alloys of iron, carbon, and silicon in which more carbon is present than can be retained in solid solution in austenite at the eutectic temperature. In gray cast iron, the carbon that exceeds the solubility in austenite precipitates as flake graphite. Gray irons usually contain 2.5 to 4% C, 1 to 3% Si, and additions of manganese, depending on the desired microstructure (as low as 0.1% Mn in ferritic gray irons and as high as 1.2% in pearlitics). Sulfur and phosphorus are also present in small amounts as residual impurities.

Certain important but low-tonnage specialty items in this family of cast metals (notably the austenitic and other highly alloyed gray irons) are not dealt with here; instead the emphasis is on the properties of gray irons used most often and in the largest tonnages. Information on the high-alloy gray irons is given in the article "Alloy Cast Irons" in this Volume.

The basic metallurgy of gray cast irons is discussed in the article "Classification and Basic Metallurgy of Cast Iron" in this Volume.

Classes of Gray Iron

A simple and convenient classification of the gray irons is found in ASTM specification A 48, which classifies the various types in terms of tensile strength, expressed in ksi. The ASTM classification by no means connotes a scale of ascending superiority from class 20 (minimum tensile strength of 140 MPa, or 20 ksi) to class 60 (minimum tensile strength of 410 MPa, or 60 ksi). In many applications strength is not the major criterion for the choice of grade. For example, for parts such as clutch plates and brake drums, where resistance to heat checking is important, low-strength grades of iron are the superior performers. Similarly, in heat shock applications such as ingot or pig molds, a class 60 iron would fail quickly, whereas good performance is shown by class 25 iron. In machine tools and other parts subject to vibration, the better damping capacity of low-strength irons is often advantageous.

Generally, it can be assumed that the following properties of gray cast irons increase with increasing tensile strength from class 20 to class 60:

- All strengths, including strength at elevated temperature
- Ability to be machined to a fine finish
- Modulus of elasticity
- Wear resistance

On the other hand, the following properties decrease with increasing tensile strength, so that low-strength irons often perform better than high-strength irons when these properties are important:

- Machinability
- Resistance to thermal shock
- Damping capacity
- Ability to be cast in thin sections

Applications

Gray iron is used for many different types of parts in a very wide variety of machines and structures. Like parts made from other metals and alloys, parts intended to be produced as gray iron castings must be evaluated for the specific service conditions before being approved for production. Often a stress analysis of prototype castings helps establish the appropriate class of gray iron as well as any proof test requirements or other acceptance criteria for production parts.

Castability

Successful production of a gray iron casting depends on the fluidity of the molten metal and on the cooling rate (which is influenced by the minimum section thickness and on section thickness variations). Casting design is often described in terms of section sensitivity. This is an attempt to correlate properties in critical sections of the casting with the combined effects of composition and cooling rate. All these factors are interrelated and may be condensed into a single term, castability, which for gray iron may be defined as the minimum section thickness that can be produced in a mold cavity with given volume/area ratio and mechanical properties consistent with the type of iron being poured.

Fluidity. Scrap losses resulting from misruns, cold shuts, and round corners are often attributed to the lack of fluidity of the metal being poured.

Mold conditions, pouring rate, and other process variables being equal, the fluidity of commercial gray irons depends primarily on the amount of superheat above the freezing temperature (liquidus). As the total carbon (TC) content decreases, the liquidus temperature increases, and the fluidity at a given pouring temperature therefore decreases. Fluidity is commonly measured as the length of flow into a spiral-type fluidity test mold. The relation between fluidity and superheat is shown in Fig. 1 for four unalloyed gray irons of different carbon contents.

Fig. 1 Fluidity versus degree of superheat for four gray irons of different carbon contents

The significance of the relationships between fluidity, carbon content, and pouring temperature becomes apparent when it is realized that the gradation in strength in the ASTM classification of gray iron is due in large part to differences in carbon content (~3.60 to 3.80% for class 20; ~2.70 to 2.95% for class 60). The fluidity of these irons thus resolves into a measure of the practical limits of maximum pouring temperature as opposed to the liquidus of the iron being poured. These practical limits of maximum pouring temperature are largely determined by three factors:

- The ability of both mold and cores to withstand the impact of molten iron, an ability that decreases as the pouring temperature increases, thereby favoring low pouring temperatures
- The fact that metal tap temperatures seldom exceed 1550 °C (2825 °F). Because ladling and reladling to the point of pouring generally accounts for temperature losses of 55 to 85 °C (100 to 150 °F), the final pouring temperatures seldom exceed 1450 to 1495 °C (2640 to 2720 °F), and in most instances maximum pouring temperatures in the range 1410 to 1450 °C (2570 to 2640 °F) are considered more realistic
- The necessity to control the overall thermal input to the mold in order to control the final desired microstructure

It can be seen from Table 1 that because of differences in liquidus temperature, the amount of superheat (and therefore fluidity) varies with carbon content when various compositions are cast from the same pouring temperature.

Table 1 Superheat above liquidus for 2% Si irons of various carbon contents poured at 1455 °C (2650 °F)

Carbon, %	Liquidus temperature	Superheat above liquidus
2.13	1200	255
2.52	1250	205
3.04	1300	155
3.60	1350	105

	°C	°F	°C	°F
2.52	1295	2360	160	290
3.04	1245	2270	210	380
3.60	1175	2150	280	500

Microstructure

The usual microstructure of gray iron is a matrix of pearlite with graphite flakes dispersed throughout. Foundry practice can be varied so that nucleation and growth of graphite flakes occur in a pattern that enhances the desired properties. The amount, size, and distribution of graphite are important. Cooling that is too rapid may produce so-called chilled iron, in which the excess carbon is found in the form of massive carbides. Cooling at intermediate rates can produce mottled iron, in which carbon is present in the form of both primary cementite (iron carbide) and graphite. Very slow cooling of irons that contain large percentages of silicon and carbon is likely to produce considerable ferrite and pearlite throughout the matrix, together with coarse graphite flakes.

Flake graphite is one of seven types (shapes or forms) of graphite established in ASTM A 247. Flake graphite is subdivided into five types (patterns), which are designated by the letters A through E (see Fig. 2). Graphite size is established by comparison with an ASTM size chart, which shows the typical appearances of flakes of eight different sizes at 100× magnification.

Fig. 2 Types of graphite flakes in gray iron (AFS-ASTM). In the recommended practice (ASTM A 247), these charts are shown at a magnification of 100×. They have been reduced to one-third size for reproduction here.

Type A flake graphite (random orientation) is preferred for most applications. In the intermediate flake sizes, type A flake graphite is superior to other types in certain wear applications such as the cylinders of internal combustion engines. Type B flake graphite (rosette pattern) is typical of fairly rapid cooling, such as is common with moderately thin sections (about 10 mm, or $\frac{3}{8}$ in.) and along the surfaces of thicker sections, and sometimes results from poor inoculation. The large flakes of type C flake graphite are typical of kish graphite that is formed in hypereutectic irons. These large flakes enhance resistance to thermal shock by increasing thermal conductivity and decreasing elastic modulus. On the other hand, large flakes are not conducive to good surface finishes on machined parts or to high strength or good impact resistance. The small, randomly oriented interdendritic flakes in type D flake graphite promote a fine machined finish by minimizing surface pitting, but it is difficult to obtain a pearlitic matrix with this type of graphite. Type D flake graphite may be formed near rapidly cooled surfaces or in thin sections. Frequently, such graphite is surrounded by a ferrite matrix, resulting in soft spots in the casting. Type E flake graphite is an interdendritic form, which has a preferred rather than a random orientation. Unlike type D graphite, type E graphite can be associated with a pearlitic matrix and thus can produce a casting whose wear properties are as good as those of a casting containing only type A graphite in a pearlitic matrix.

There are, of course, many applications in which flake type has no significance as long as the mechanical property requirements are met.

Solidification of Gray Iron. In a hypereutectic gray iron, solidification begins with the precipitation of kish graphite in the melt. Kish grows as large, straight, undistorted flakes or as very thick, lumpy flakes that tend to rise to the surface of the melt because of their low relative density. When the temperature has been lowered sufficiently, the remaining liquid solidifies as a eutectic structure of austenite and graphite. Generally, eutectic graphite is finer than kish graphite.

In hypoeutectic iron, solidification begins with the formation of proeutectic austenite dendrites. As the temperature falls, the dendrites grow, and the carbon content of the remaining liquid increases. When the increasing carbon content and decreasing temperature reach eutectic values, eutectic solidification begins. Eutectic growth from many different nuclei proceeds along crystallization fronts that are approximately spherical. Ultimately, the eutectic cells meet and consume the liquid remaining in the spaces between them. During eutectic solidification, the austenite in the eutectic becomes continuous with the dendritic proeutectic austenite, and the structure can be described as a dispersion of graphite flakes in austenite. After solidification, the eutectic cell structure and the proeutectic austenite dendrites cannot be distinguished metallographically except by special etching or in strongly hypoeutectic iron.

With eutectic compositions, obviously, solidification takes place as the molten alloy is cooled through the normal eutectic temperature range, but without the prior formation of a proeutectic constituent. During the solidification process, the controlling factor remains the rate at which the solidification is proceeding. The rapid solidification favored by thin section sizes or highly conductive molding media can result in undercooling. Undercooling can cause the solidification to start at a temperature lower than the expected eutectic temperature for a given composition (Fig. 3). This can result in a modification of the carbon form from A to E type or can completely suppress its formation and form primary carbides instead.

Fig. 3 Undercooling from rapid cooling of a eutectic composition

Room-Temperature Structure. Upon cooling from the eutectic temperature, the austenite will decompose, first by precipitating some of the dissolved carbon and then, at the eutectoid temperature, by undergoing complete transformation. The actual products of the eutectoid transformation depend on rate of cooling as well as on composition of the austenite, but under normal conditions the austenite will transform either to pearlite or to ferrite plus graphite.

Transformation to ferrite plus graphite is most likely to occur with slow cooling rates, which allow more time for carbon migration within the austenite; high silicon contents, which favor the formation of graphite rather than cementite; high values of carbon equivalent; and the presence of fine undercooled (type D) flake graphite. Graphite formed during decomposition is deposited on the existing graphite flakes.

When carbon equivalent values are relatively low or when cooling rates are relatively fast, the transformation to pearlite is favored. In some instances, the microstructure will contain all three constituents: ferrite, pearlite, and graphite. With certain compositions, especially alloy gray irons, it is possible to produce a martensitic matrix by oil quenching through the eutectoid transformation range or an austempered matrix by appropriate isothermal treatment (Ref 1). These treatments are often done deliberately in a secondary heat treatment where high strength or hardness is especially desired, such as in certain wear applications. The secondary heat treatment of gray iron castings is of great value in producing components that must be hard when machining requirements prohibit the use of components that are cast to final shape in white iron.

Section Sensitivity

In practice, the minimum thickness of section in which any given class of gray iron may be poured is more likely to depend on the cooling rate of the section than on the fluidity of the metal. For example, although a plate 300 mm (12 in.) square by 6 mm (0.24 in.) thick can be poured in class 50 as well as in class 25 iron, the former casting would not be gray iron because the cooling rate would be so rapid that massive carbides would be formed. Yet it is entirely feasible to use class 50 iron for a diesel engine cylinder head that has predominantly 6 mm (0.24 in.) wall sections in the water jackets above the firing deck. This is simply because the cooling rate of the cylinder head is reduced by the "mass effect" resulting from enclosed cores and the proximity (often less than 12 mm, or 0.47 in.) of one 6 mm (0.24 in.) wall to the other. Thus the shape of the casting has an important bearing on the choice of metal specification.

It should be recognized that the smallest section that can be cast gray, without massive carbides, depends not only on metal composition, but also on foundry practices. For example, by adjusting silicon content or by using graphitizing additions called inoculants in the ladle, the foundryman can decrease the minimum section size for freedom from carbides for a given basic composition of gray iron.

The mass effect associated with increasing section thickness or decreasing cooling rate is much more pronounced in gray iron than in cast steel. The mass effect in cast steel results in increased grain size in heavy sections. This also applies to gray iron, but the most important effects are on graphite size and distribution, and on amount of combined carbon.

For any given gray iron composition, the rate of cooling from the freezing temperature to below about 650 °C (1200 °F) determines the ratio of combined to graphitic carbon, which controls the hardness and strength of the iron. For this reason the effect of section size in gray iron is considerably greater than in the more homogeneous ferrous metals in which cooling rate does not affect the form and distribution of carbon throughout the metal structure.

Typical Effects of Section Size. When a wedge-shape bar with about a 10° taper is cast in a sand mold and sectioned near the center of the length, and Rockwell hardness determinations are made on the cut surface from the point of the wedge progressively into the thicker sections, the curves so determined show to what extent continually increasing section size affects hardness (Fig. 4).

Fig. 4 Effect of section thickness on hardness and structure. Hardness readings were taken at increasing distance from the tip of a cast wedge section, as shown by inset. Composition of iron: 3.52% C, 2.55% Si, 1.01% Mn, 0.215% P, and 0.086% S. Source: Ref 2

Progressing along the curve from the left in Fig. 4, the following metallographic constituents occur. The tip of the wedge is white iron (a mixture of carbide and pearlite) with a hardness greater than 50 HRC. As the iron becomes mottled (a mixture of white iron and gray iron), the hardness decreases sharply. A minimum is reached because of the occurrence of fine type D flake graphite, which usually has associated ferrite in large amounts. With a slightly lower cooling rate, the structure becomes fine type A flake graphite in a pearlite matrix with the hardness rising to another maximum on the curve. This structure is usually the most desirable for wear resistance and strength. With increasing section thickness beyond this point, the graphite flakes become coarser, and the pearlite lamellae become more widely spaced, resulting in slightly lower hardness. With further increase in wedge thickness and decrease in cooling rate, pearlite decomposes progressively to a mixture of ferrite and graphite, resulting in softer and weaker iron.

The structures of most commercial gray iron castings are represented by the right-hand downward-sloping portion of the curve in Fig. 4, beyond 5 mm (0.2 in.) wedge thickness, and increasing section size is normally reflected by the gradual lowering of hardness and strength. However, thin sections may be represented by the left-hand downward-sloping portion.

Figure 5 shows the average tensile strength (up to ten tests per point) of two irons, for each of which six sizes of cylindrical round bars were cast and appropriate tensile specimens machined. With the class 20 iron, strength increases as the as-cast section decreases down to the 6 mm (0.24 in.) cast bar. However, for the class 30 iron, a section 6 mm (0.24 in.) in diameter is so small that the strength falls off sharply, because of the occurrence of type D flake graphite or mottled iron, or both. The other graph in Fig. 5 shows similar data for the same two classes of iron and for three higher classes.

Fig. 5 Effect of section diameter on tensile strength at center of cast specimen for five classes of gray iron

Section sensitivity effects are used in the form of a wedge test in production control to judge the suitability of an iron for pouring a particular casting. In this test, a wedge-shape casting is poured and upon solidification is evaluated. The standard W2 wedge block specified in ASTM A 367 is shown in Fig. 6. The evaluation consists of measuring the length of the "chilled zone." The measurement, usually made in 0.8 mm ($\frac{1}{32}$ in.) increments, is related to empirically determined data obtained from a "good" casting. If the evaluation indicates an excessive sensitivity for a part, corrections are made to the molten metal prior to pouring.

Fig. 6 Standard W2 wedge block used for measuring depth of chill (ASTM A 367). Dimensions given in inches

Volume/Area Ratios. It is extremely difficult to predict with accuracy the cooling rate for castings other than fairly simple shapes. However, because minimum limitations are involved here, the problem can be resolved through comparisons of the casting design with ratios of volume to surface area or with minimum plate sections.

The volume/area (V/A) ratios for round, square, and plate sections provide a fairly accurate indication of the minimum casting sections possible in simple geometrical shapes (Table 2). The V/A ratios can be reported in either English or metric units and can be converted simply by treating them as length measurements.

Table 2 Volume/area (V/A) ratios for round bars, square bars, and plates

Cast form and size	V/A ratio	
	mm	in.
Bar, 13 mm ($\frac{1}{2}$ in.) diam \times 533 mm (21 in.)	3.1	0.12
Bar, 13 mm ($\frac{1}{2}$ in.) square \times 533 mm (21 in.)	3.1	0.12
Plate, 6.4 \times 305 \times 305 mm ($\frac{1}{4}$ \times 12 \times 12 in.)	3.0	0.12
Bar, 30 mm (1.2 in.) diam \times 533 mm (21 in.) ^(a)	7.4	0.29
Bar, 30 mm (1.2 in.) square \times 533 mm (21 in.)	7.4	0.29
Plate, 16 \times 305 \times 305 mm ($\frac{5}{8}$ \times 12 \times 12 in.)	7.1	0.28

Bar, 50 mm (2 in.) diam × 560 mm (22 in.)	12.2	0.48
Bar, 50 mm (2 in.) square × 560 mm (22 in.)	12.2	0.48
Plate, 28.5 × 305 × 305 mm ($1\frac{1}{8} \times 12 \times 12$ in.)	12.0	0.47
Bar, 100 mm (4 in.) diam × 460 mm (18 in.)	22.9	0.90
Bar, 100 mm (4 in.) square × 460 mm (18 in.)	22.9	0.90
Plate, 65 × 305 × 305 mm ($2\frac{9}{16} \times 12 \times 12$ in.)	22.8	0.90
Bar, 150 mm (6 in.) diam × 460 mm (18 in.)	32.7	1.29
Bar, 150 mm (6 in.) square × 460 mm (18 in.)	32.7	1.29
Plate, 114 × 305 × 305 mm ($4\frac{1}{2} \times 12 \times 12$ in.)	32.7	1.29

Source: Ref 3

(a) ASTM size B test bar

Comparison of the ratios of volume to surface area for different shapes gives good agreement with the actual cooling rates of castings made in the same mold material. For long round bars and infinite flat plates, V/A is diameter/4 for bars and thickness/2 for plates; that is, a large plate casting would have the same cooling rate as a round bar with a diameter twice the plate thickness. Most castings, however, freeze somewhat faster than an infinite flat plate, and rather than establishing a 2-to-1 ratio of bar to plate, a smaller ratio will often give a better correlation with the cooling rate. The bar and plate sizes shown in Table 3 are nearly equivalent in cooling rate.

Table 3 Bar and plate sizes of equivalent cooling rate

For 305 mm (12 in.) square plates, as recorded in Table 2

Bar diameter, in.	Plate thickness, in.	Ratio of bar diameter to plate thickness
$\frac{1}{2}$	$\frac{1}{4}$	2.0
1.2	$\frac{5}{8}$	1.92

2	$1\frac{1}{8}$	1.78
4	$2\frac{9}{16}$	1.56
6	$4\frac{1}{2}$	1.33

Similar comparisons have been made for production castings. In one study, the properties of a flat section from a 0.6 m (24 in.) cross pipe fitting having a nominal thickness of 29.5 mm (1.16 in.) were compared with the properties of a 50 mm (2 in.) diam cylindrical test bar cast from the same heat. The tensile strengths of the test bars were within about 16 MPa (2.3 ksi) of the tensile strengths of the cross pipe fittings for eight heats ranging in strength from about 205 to 310 MPa (30 to 45 ksi), an average variation of less than 8%. These results from production castings correlate well with the calculated equivalence given in Table 3. Other examples of this type of correlation are given in Ref 3.

Relationships developed for various specific castings are valid when an iron of controlled composition, and therefore of similar section sensitivity, is used consistently. For instance, with a copper-molybdenum iron of well-controlled composition, a tensile strength of 450 MPa (65 ksi) in the ASTM B test specimen has been found to ensure 345 MPa (50 ksi) tensile strength in a cast crankshaft 2.13 m (7 ft) long with sections thicker than 30.5 mm (1.2 in.). Such translation of properties of a small test bar to properties expected in a larger section cannot be done indiscriminately, because different irons may vary widely in section sensitivity.

Prevailing Sections

Although the ASTM size B test bar (30.5 mm, or 1.2 in., diam) is the bar most commonly used for all gray irons from class 20 to class 60, ASTM specification A 48 provides a series of bar sizes from which one that approximates the cooling rate in the critical section of the casting can be selected. In practice, it is customary to be somewhat more definite regarding the prevailing values of minimum casting section considered feasible for the various ASTM classes of cast iron. As summarized in Table 4, these minimum, prevailing sections include the requirement of freedom from carbide areas. In a platelike section, occasional thinner walls (such as ribs) are of no importance unless they are very thin or are appended to the outer edges of the casting.

Table 4 Minimum prevailing casting sections recommended for gray irons

ASTM A48 class	Minimum thickness		V/A ratio ^(a)	
	in.	mm	in.	mm
20	$\frac{1}{8}$	3.2	0.06	1.5

25	$\frac{1}{4}$	6.4	0.12	3.0
30	$\frac{3}{8}$	9.5	0.17	4.3
35	$\frac{3}{8}$	9.5	0.17	4.3
40	$\frac{5}{8}$	15.9	0.28	7.1
50	$\frac{3}{4}$	19.0	0.33	8.4
60	1	25.4	0.42	10.7

(a) V/A ratios are for square plates.

Mechanical properties of class 30 and class 50 gray irons in various sections are shown in Fig. 7. For class 30 iron, the combined carbon content and hardness are still at a safe level in sections equivalent to a 10 mm (0.4 in.) plate, which has a V/A ratio of about 5 mm (0.20 in.). For class 50 iron, however, both combined carbon and Brinell hardness show marked increases when the thickness of the equivalent plate section is decreased to about 15 mm (0.6 in.), with V/A ratio around 7 mm (0.27 in.). These results are consistent with the minimum prevailing casting sections recommended in Table 4.

Fig. 7 Mechanical properties of class 30 and class 50 gray iron as a function of section size. Composition of the class 30 iron: 3.40% C, 2.38% Si, 0.71% Mn, 0.423% P, and 0.152% S; for the class 50 iron: 2.96% C, 1.63% Si, 1.05% Mn, 0.67% Mo, 0.114% P, and 0.072% S. Source: Ref 4

The hazards involved in pouring a given class of gray iron in a plate section thinner than recommended are discovered when the casting is machined. Typical losses as a result of specifying too high a strength for a prevailing section of 9.5 mm ($\frac{3}{8}$ in.) are given below (rejections were for "hard spots" that made it impossible to machine the castings by normal methods):

Class	Rejections, %
35	Negligible
45	25

55	80-100
----	--------

In marginal applications, a higher class of iron may sometimes be used if the casting is cooled slowly (in effect, increasing the section thickness) by judicious placement of flow-offs and risers. An example is the successful production of a 25 mm (1 in.) diam single-throw crankshaft for an air compressor. This shaft was hard at the extreme ends when poured in class 50 iron. The difficulty was corrected by flowing metal through each end into flow-off risers that adequately balanced the cooling rate at the ends with the cooling rate at the center.

In sum, the selection of a suitable grade of gray iron for a specific casting necessarily requires an evaluation of the size and shape of the casting as related to its cooling rate, or volume/area ratio. For a majority of parts, this evaluation need be no more than a determination of whether or not the V/A ratio of the casting exceeds the minimum V/A ratio indicated for the grade considered.

Test Bar Properties

Mechanical property values obtained from test bars are sometimes the only available guides to the mechanical properties of the metal in production castings. When test bars and castings are poured from metal of the same chemical history, correlations can be drawn between the thermal history of the casting and that of the test bar. The strength of the test bar gives a relative strength of the casting, corrected for the cooling rate of the various section thickness. Through careful analysis of the critical sections of a casting, accurate predictions of mechanical behavior can be achieved.

Usual Tests. Tension and transverse tests on bars that are cast specifically for such tests are the most common methods used for evaluating the strength of gray iron.

Yield strength, elongation, and reduction of area are seldom determined for gray iron in standard tension tests. The transverse test measures strength in bending and has the additional advantage that a deflection value may be obtained readily. Minimum specification values are given in Table 5. Data can usually be obtained faster from the transverse test than from the tension test because machining of the specimen is unnecessary. The surface condition of the bar will affect the transverse test but not the tension test made on a machined specimen. Conversely, the presence of coarse graphite in the center of the bar, which can occur in an iron that is very section sensitive, will affect the tension test but not the transverse test.

Table 5 Transverse breaking loads of gray irons tested per ASTM A 438

ASTM class ^(a)	Approximate tensile strength		Corrected transverse breaking load ^(a)					
			A bar ^(b)		B bar ^(c)		C bar ^(d)	
	MPa	ksi	kg	lb	kg	lb	kg	lb
20	138	20	408	900	816	1800	2720	6,000
25	172	25	465	1025	907	2000	3080	6,800
30	207	30	522	1150	998	2200	3450	7,600

35	241	35	578	1275	1089	2400	3760	8,300
40	276	40	635	1400	1179	2600	4130	9,100
45	310	45	699	1540	1270	2800	4400	9,700
50	345	50	760	1675	1361	3000	4670	10,300
60	414	60	873	1925	1542	3400	5670	12,500

- (a) For separately cast test specimens produced in accordance with ASTM A 48, ASTM A 278, ASME SA278, FED QQ-1-652, or any other specification that designates ASME A438 as the test method. Included in specifications only by agreement between producer and purchaser.
- (b) 22.4 mm (0.88 in.) diam; 305 mm (12 in.) between supports.
- (c) 30.5 mm (1.20 in.) diam; 460 mm (18 in.) between supports.
- (d) 50.8 mm (2.00 in.) diam; 610 mm (24 in.) between supports.

Hardness tests, on either test bars or castings, are used as an approximate measure of strength and sometimes as an indication of relative machinability. Relationships between Brinell hardness and tensile strength generally follow the pattern reproduced in Fig. 8, which shows the variation of tensile strength with Brinell hardness for a series of gray irons produced by a single foundry. The data in Fig. 8 are from ASTM size A and B test bars poured in a series of inoculated gray irons. The successful use of Brinell hardness as a measure of strength depends on whether it can be proved suitable for the application, which may involve service tests or mechanical property tests on specimens cut from production castings.

Fig. 8 Relationship between tensile strength and Brinell hardness for a series of inoculated gray irons from a single foundry. Open circles represent unalloyed gray iron, and closed circles represent alloy gray iron. Source: Ref 5

Testing Precautions. In the assessment of mechanical properties for a series of heats, precautions should be taken to ensure minimum statistical variation between bars. By its nature gray iron behaves as a brittle material in tension, with no measurable elongation after fracture. This characteristic can be exaggerated by imposing a nonaxial load during tensile testing, resulting in statistical variations, which may not be a true measure of the quality of the iron. To overcome this tendency, many shops use self-aligning nonthreaded grips in the performance of tensile tests on gray iron test bars.

Typical Specifications. ASTM A 48 is typical of specifications based on test bars. In practice, one of three different standard sizes of separately cast test bars is used to evaluate the properties in the controlling section of the castings. After manufacturer and purchaser agree on a controlling section of the casting, the size of test bar that corresponds, approximately, to the cooling rate expected in that section is designated by a letter (see Table 6).

Table 6 Test bars designed to match controlling sections of castings (ASTM A 48)

Controlling section		Test bar	Diameter of as-cast test bar	
in.	mm		mm	in.
<0.25	<6	S	(a)	(a)
0.25-0.50	6-12	A	22.4	0.88
0.51-1.00	13-25	B	30.5	1.20
1.01-2.00	26-50	C	50.8	2.00

(a) All dimensions of test bar by agreement between manufacturer and purchaser

Most gray iron castings for general engineering use are specified as either class 25, 30, or 35. Specification A 48 is based entirely on mechanical properties, and the composition that provides the required properties can be selected by the individual producer. A manufacturer whose major production is medium-section castings of class 35 iron will find, for heavy-section castings for which the 50 mm (2 in.) test bar is required for qualifying, that the same composition will not meet the requirements for class 35. It will qualify only for some lower class, such as 25 or 30. As the thickness of the controlling section increases, the composition must be adjusted to maintain the same tensile strength.

SAE standard J431c for gray cast irons (see Tables 7, 8, 9, and 10) describes requirements that are more specific than those described in ASTM A 48. An iron intended for heavy sections, such as grade G3500, is specified to have higher strength and hardness in the standard test bar than does grade G2500, which is intended for light-section castings. Typical applications for the various grades are summarized in Table 11.

Table 7 Mechanical properties of SAE J431 automotive gray cast irons

Properties determined from as-cast test bar B (30.5 mm, or 1.2 in., diam)

SAE grade	Hardness, HB	Minimum transverse load		Minimum deflection		Minimum tensile strength	
		kg	lb	mm	in.	MPa	ksi
G1800	187 max	780	1720	3.6	0.14	124	18
G2500	170-229	910	2000	4.3	0.17	173	25
G3000	187-241	1000	2200	5.1	0.20	207	30
G3500	207-255	1110	2450	6.1	0.24	241	35
G4000	217-269	1180	2600	6.9	0.27	276	40

Table 10 Typical base compositions of SAE J431 automotive gray cast irons for heavy-duty service

See Table 9 for mechanical properties.

UNS	SAE grade	Composition, % ^(a)				
		TC	Mn	Si	P	S
F10009	G2500a ^(b)	3.40 min	0.60-0.90	1.60-2.10	0.12	0.12
F10010	G3500b ^(c)	3.40 min	0.60-0.90	1.30-1.80	0.80	0.12
F10011	G3500c ^(c)	3.50 min	0.60-0.90	1.30-1.80	0.80	0.12

(a) If either carbon or silicon is on the high side of the range, the other should be on the low side. Alloying elements not listed in this table may be required.

(b) Microstructure: size 2 to 4 type A graphite in a matrix of lamellar pearlite containing not more than 15% free ferrite.

(c) Microstructure: size 3 to 5 type A graphite in a matrix of lamellar pearlite containing not more than 5% free ferrite or free carbide.

(d) Alloy gray iron containing 0.85 to 1.25% Cr, 0.40 to 0.60% Mo, and 0.20 to 0.45% Ni or as agreed. Microstructure: primary carbides and size 4 to 7 type A or E graphite in a matrix of fine pearlite, as determined in a zone at least 3.2 mm ($\frac{1}{8}$ in.) deep at a specified location on a cam surface.

Table 11 Automotive applications of gray cast iron

Grade	Typical uses
G1800	Miscellaneous soft iron castings (as-cast or annealed) in which strength is not a primary consideration
G2500	Small cylinder blocks, cylinder heads, air-cooled cylinders, pistons, clutch plates, oil pump bodies, transmission cases, gearboxes, clutch housings, and light-duty brake drums
G2500a	Brake drums and clutch plates for moderate service requirements, where high-carbon iron is desired to minimize heat checking
G3000	Automobile and diesel cylinder blocks, cylinder heads, flywheels, differential carrier castings, pistons, medium-duty brake drums and clutch plates
G3500	Diesel engine blocks, truck and tractor cylinder blocks and heads, heavy flywheels, tractor transmission cases, heavy gearboxes
G3500b	Brake drums and clutch plates for heavy duty service where both resistance to heat checking and higher strength are definite requirements
G3500c	Brake drums for extra heavy duty service
G4000	Diesel engine castings, liners, cylinders, and pistons
G4000d	Camshafts

ASTM specifications other than A 48 include A 159 (automotive), A 126 (valves, flanges, and pipe fittings), A 74 (soil pipe and fittings), A 278 (pressure-containing parts for temperatures up to 340 °C, or 650 °F), A 319 (nonpressure-containing parts for elevated-temperature service) and A 436 (austenitic gray irons for heat, corrosion, and wear resistance). The austenitic gray irons are described in the article "Alloy Cast Irons" in this Volume. ASTM A 438 describes the standard method for performing transverse bending tests on separately cast, cylindrical test bars of gray cast iron.

Compressive Strength. When gray iron is used for structural applications such as machinery foundations or supports, the engineer, who is usually designing, to support weight only, bases his calculations on the compressive strength of the material. Table 12, which summarizes typical values for mechanical properties of the various grades, shows the high compressive strength of gray irons. Figure 9 compares the stress-strain curves in tension and compression for a class 20 and a class 40 gray iron. The compressive strength of gray iron is typically three to four times that of the tensile strength. If loads other than dead weights are involved (unless these loads are constant), the problem is one of dynamic stresses, which requires the consideration of fatigue and damping characteristics.

Table 12 Typical mechanical properties of as-cast standard gray iron test bars

ASTM A 48 class	Tensile strength		Torsional shear strength		Compressive strength		Reversed bending fatigue limit		Transverse load on test bar B		Hardness, HB
	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi	kg	lb	

20	152	22	179	26	572	83	69	10	839	1850	156
25	179	26	220	32	669	97	79	11.5	987	2175	174

Source: Ref 6

Tensile strength is considered in selecting gray iron for parts intended for static loads in direct tension or bending. Such parts include pressure vessels, autoclaves housings and other enclosures, valves, fittings, and levers. Depending on the uncertainty of loading, safety factors of 2 to 12 have been used in figuring allowable design stresses.

Transverse Strength and Deflection. When an ASTM arbitration bar is loaded as a simple beam and the load and deflection required to break it are determined, the resulting value is converted into a nominal index of strength by using the standard beam formula. The value that is determined is arbitrarily called the modulus of rupture. The values for modulus of rupture are useful for production control, but cannot be used in the design of castings without further analysis and interpretation. Rarely does a casting have a shape such that those areas subject to bending stress have a direct relationship to the round arbitration bar. A more rational approach is to use the tensile strength (or fatigue limit) and, after determining the section modulus of the actual shape, apply the proper bending formula. However, because the difficulty of obtaining meaningful values of tensile strength in tests of small specimens, the load computed in this manner is usually somewhat lower than the actual load required to rupture the part, unless unfavorable residual stresses are present in the finished part.

Elongation of gray iron at fracture is very small (of the order of 0.6%) and hence is seldom reported. The designer cannot use the numerical value of permanent elongation in any quantitative manner.

Torsional Shear Strength. As shown in Table 12, most gray irons have high torsional shear strength. Many grades have torsional strength greater than that of some grades of steel. This characteristic, along with low notch sensitivity, makes gray iron a suitable material for shafting of various types, particularly in the grades of higher tensile strength. Most shafts are subjected to dynamic torsional stresses, and the designer should carefully consider the exact nature of the loads to be encountered. For the higher-strength irons, stress concentration factors associated with changes of shape in the part are important for torque loads as well as for bending and tension loads.

Modulus of Elasticity. Typical stress-strain curves for gray iron are shown in Fig. 10. Gray iron does not obey Hooke's law, and the modulus in tension is usually determined arbitrarily as the slope of the line connecting the origin of the stress-strain curve with the point corresponding to one-fourth the tensile strength (secant modulus). Some engineers use the slope of the stress-strain curve near the origin (tangent modulus). The secant modulus is a conservative value suitable for most engineering work; design loads are seldom as high as one-fourth the tensile strength, and the deviation of the stress-strain curve from linearity is usually less than 0.01% at these loads. However, in the design of certain types of machinery, such as precision equipment, where design stresses are very low, the use of the tangent modulus may represent the actual situation more accurately.

Fig. 10 Typical stress-strain curves for three classes of gray iron in tension

The modulus of gray iron (see Table 13) varies considerably more than do the moduli for most other metals. Thus, in using observed strain to calculate stress, it is essential to measure the modulus of the particular gray iron specimen being considered. A significant range in modulus values is experienced because of both section size and chemical analysis variations (Fig. 11). In addition, the modulus experiences a linear reduction with increasing temperature. The rate of

reduction can be reduced through alloy additions (Fig. 12). The numerical value of the modulus in torsion is always less than it is in tension, as is the case with steel.

Table 13 Typical moduli of elasticity of as-cast standard gray iron test bars

ASTM A 48 class	Tensile modulus		Torsional modulus	
	GPa	10 ⁶ psi	GPa	10 ⁶ psi
20	66-97	9.6-14.0	27-39	3.9-5.6
25	79-102	11.5-14.8	32-41	4.6-6.0
30	90-113	13.0-16.4	36-45	5.2-6.6
35	100-119	14.5-17.2	40-48	5.8-6.9
40	110-138	16.0-20.0	44-54	6.4-7.8
50	130-157	18.8-22.8	50-55	7.2-8.0

Fig. 11 Interrelationship of mechanical properties, section diameter, carbon equivalent, and liquidus temperature of gray iron. Data are from one foundry and are based on dry sand molding and ferrosilicon inoculation.

Fig. 12 Elastic modulus as a function of temperature in various alloyed gray cast irons. Source: Ref 7

Hardness of gray iron, as measured by Brinell or Rockwell testers, is an intermediate value between the hardness of the soft graphite in the iron and that of the harder metallic matrix. Variations in graphite size and distribution will cause wide variations in hardness (particularly Rockwell hardness) even though the hardness of the metallic matrix is constant. To illustrate this effect, the matrix microhardness of five types of hardened iron are compared with Rockwell C measurements on the same iron in Table 14.

Table 14 Influence of graphite type and distribution on the hardness of hardened gray irons

Type of graphite	Total carbon, %	Conventional hardness, HRC ^(a)	Matrix hardness, HRC ^(b)
A	3.06	45.2 ^(c)	61.5
A	3.53	43.1	61.0
A	4.00	32.0	62.0
D	3.30	54.0	62.5
D	3.60	48.7	60.5

(a) Measured by conventional Rockwell C test.

(b) Hardness of matrix, measured with superficial hardness tester and converted to Rockwell C.

(c) Although this value was obtained in the specific test cited, it is not typical of gray iron of 3.06% C. Ordinarily the hardness of such iron is 48 to 50 HRC.

If any hardness correlation is to be attempted, the type and amount of graphite in the irons being compared must be constant. Rockwell hardness tests are considered appropriate only for hardened castings (such as camshafts), and even on hardened castings, Brinell tests are preferred. Brinell tests must be used when attempting any strength correlations for unhardened castings.

Fatigue Limit in Reversed Bending

Because fatigue limits are expensive to determine, the designer usually has incomplete information on this property. Fatigue life curves at room temperature for a gray iron under completely reversed cycles of bending stress are shown in Fig. 13(a), in which each point represents the data from one specimen. The effects of temperature on fatigue limit and tensile strength are shown in Fig. 13(b) and 13(c), respectively.

Fig. 13 Effect of temperature on fatigue behavior and tensile strength of a gray iron (2.84% C, 1.52% Si, 1.05% Mn, 0.07% P, 0.12% S, 0.31% Cr, 0.20% Ni, 0.37% Cu). (a) Reversed bending fatigue life at room temperature. (b) Reversed bending fatigue limit at elevated temperatures. (c) Tensile strength at elevated temperatures. Source: Ref 8

Axial loading or torsional loading cycles are frequently encountered in designing parts of cast iron, and in many instances these are not completely reversed loads. Types of regularly repeated stress variation can usually be expressed as a function of a mean stress and a stress range. Wherever possible, the designer should use actual data from the limited information available. Without precisely applicable test data, an estimate of the reversed bending fatigue limit of machined parts may be made by using about 35% of the minimum specified tensile strength of the particular grade of gray iron being considered. This value is probably more conservative than an average of the few data available on the fatigue limit for gray iron.

An approximation of the effect of range of stress on fatigue limit may be obtained from diagrams such as Fig. 14. Tensile strength is plotted on the horizontal axis to represent fracture strength under static load (which corresponds to a 0 stress range). Reversed bending fatigue limit is plotted on the ordinate for 0 mean stress, and the two points are joined by a straight line. The resulting diagram yields a fatigue limit (maximum value of alternating stress) for any value of mean stress.

Fig. 14 Diagram showing safe and unsafe fatigue zones for cast iron subjected to ranges of alternating stress superimposed on a mean stress. Example point P shows conditions of tensile (positive) mean stress; P' shows compressive (negative) mean stress. The safety factor is represented by the ratio of OF to OP or OF' to OP' . For conditions of constant mean tensile stress, DK/DP is the safety factor.

Few data available are applicable to design problems involving dynamic loading where the stress cycle is predominantly compressive rather than tensile. Some work done on aluminum and steel indicates that for compressive (negative) mean stress, the behavior of these materials could be represented by a horizontal line beginning at the fatigue limit in reversed bending, as indicated in Fig. 14. Gray iron is probably at least as strong as this for loading cycles resulting in negative mean stress, because it is much stronger in static compression than in static tension. It is therefore a natural assumption that the parallel behavior shown in Fig. 14 is conservative.

If, prior to design, the real stress cycle can be predicted with confidence and enough data are available for a reliable $S-N$ diagram for the gray iron proposed, the casting might be dimensioned to obtain a minimum safety factor of two based on fatigue strength. (Some uses may require more conservative or more liberal loading.) The approximate safety factor is best illustrated by point P in Fig. 14. The safety factor is determined by the distance from the origin to the fatigue limit line along a ray through the cyclic-stress point, divided by the distance from the origin to that point. In Fig. 14 this is OF/OP .

On this diagram, point P' represents a stress cycle having a negative mean stress. In other words, the maximum compressive stress is greater than the tensile stress reached during the loading cycle. In this instance, the safety factor is the distance OF'/OP' . However, this analysis assumes that overloads will increase the mean stress and alternating stress in the same proportion. This may not always be true, particularly in systems with mechanical vibration in which the mean stress may remain constant. For this condition, the vertical line through P would be used; that is, DK/DP would be the factor of safety.

Most engineers use diagrams such as Fig. 14 mainly to determine whether a given condition of mean stress and cyclic stress results in a design safe for infinite life. The designer can also determine whether variations in the mean stress and the alternating stress that he anticipates will place his design in the unsafe zone. Usually the data required to analyze a particular set of conditions are obtained experimentally. It is emphasized that the number of cycles of alternating stress implied in Fig. 14 is the number normally used to determine fatigue limits, that is, approximately 10 million. Fewer

cycles, as encountered in infrequent overloads, will be safer than indicated by a particular point plotted on a diagram for infinite life. Too few data are available to draw a diagram for less than infinite life.

Fatigue Notch Sensitivity. In general, very little allowance need be made for a reduction in fatigue strength caused by notches or abrupt changes of section in gray iron members. The low-strength irons exhibit only a slight reduction in strength in the presence of fillets and holes. That is, the notch sensitivity index approaches 0; in other words, the effective stress concentration factor for these notches approaches 1. This characteristic can be explained by considering the graphite flakes in gray iron to be internal notches. Thus, gray iron can be thought of as a material that is already full of notches and that therefore has little or no sensitivity to the presence of additional notches resulting from design features. The strength-reducing effect of the internal notches is included in the fatigue limit values determined by conventional laboratory tests with smooth bars. High-strength irons usually exhibit greater notch sensitivity, but probably not the full theoretical value represented by the stress concentration factor. Normal stress concentration factors (see Ref 9) are probably suitable for high-strength gray irons.

Pressure Tightness

Gray iron castings are used widely in pressure applications such as cylinder blocks, manifolds, pipe and pipe fittings, compressors, and pumps. An important design factor for pressure tightness is uniformity of section. Parts of relatively uniform wall section cast in gray iron are pressure tight against gases as well as liquids. Most trouble with leaking castings is encountered when there are unavoidable, abrupt changes in section. Shrinkage, internal porosity, stress cracking, and other defects are most likely to occur at junctions between heavy and light sections.

Watertight castings are considerably less challenging to the foundryman than gastight castings. A slight sponginess or internal porosity at heavy sections will not usually leak water, and even if there is slight seepage, internal rusting will soon plug the passages permanently. For gastightness, however, castings must be quite sound.

Lack of pressure tightness in gray iron castings can usually be traced to internal porosity, which also is called internal shrinkage. In gray iron this seems to be a phenomenon distinctly different from the normal solidification shrinkage that often appears on the casting surface as a sink or draw, which can be cured by risering. Internal porosity or shrinkage (very difficult to prevent, even by the use of very heavy risers) is usually associated with poor feeding and lack of directional solidification. It can also be associated with heavy inoculation with calcium to promote a high graphite cell count. On the other hand, the use of strontium-bearing inoculants does not reduce cell size and can help control internal shrinkage in marginally gated castings.

Visible internal porosity may appear at centers of mass when the phosphorus content exceeds 0.25%. In critically gated castings, visible internal porosity may appear when the phosphorus content is as low as 0.09%. Chromium and molybdenum accentuate this effect of phosphorus, while nickel has a slight mitigating influence.

The effect of phosphorus may be caused in part by the fact that lowering phosphorus content also lowers the effective carbon equivalent. Lowering carbon equivalent by reducing carbon or silicon, or both, instead of phosphorus, might similarly reduce the leakage of pressure castings, but other foundry problems (such as increasing amounts of normal shrinkage) would be encountered. ASTM A 278 for pressure castings requires a carbon equivalent of 3.8% (max), a phosphorus content of 0.25% (max), and a sulfur content of 0.12% (max) for castings to be used above 230 °C (450 °F).

In addition to composition control, good overall foundry practice is required for consistently producing pressure-tight castings. Sand properties and gating must be controlled to avoid sand inclusions. Pouring temperature must be adequate for good fluidity, and heavy sections should be fed wherever possible.

Mold properties have been found to interact with composition to influence internal soundness. Generally, molds rammed tightly produce the soundest castings because of freedom from mold wall movement during solidification.

Impact Resistance

Where high impact resistance is needed, gray iron is not recommended. Gray iron has considerably lower impact strength than cast carbon steel, ductile iron, or malleable iron. However, many gray iron castings need some impact strength to resist breakage in shipment or use.

There is incomplete agreement on a standard method of impact testing for cast iron. Two methods that have been used successfully are given in ASTM A 327. Most impact testing of cast iron has been used as a research tool.

Most producers of cast iron pressure pipe use a routine pipe impact test as a control. Impact resistance in pipe helps avoid breakage in shipping and handling.

Machinability

The machinability of most gray cast iron is superior to that of most other cast irons of equivalent hardness, as well as to that of virtually all steel. The flake graphite introduces discontinuities in the metal matrix, which act as chip breakers. The graphite itself serves as a lubricant for the cutting tool. However, economical cutting depends on more than inherent machinability alone. Often, trouble in machining gray iron can be traced to one or more of several factors: the presence of chill of corners and in light sections, the presence of adhering sand on the surface of the casting, swells, usually the result of soft molds, shifted castings, shrinks, and phases included in the matrix as a result of melting practice.

Chill at corners and in light sections is more likely to be encountered with small castings, with higher-strength irons, and with designs that have light sections in the cope (or top) of the mold. Most foundries control iron with a chill test that gives an indication of the tendency of the iron to form white or mottled iron in light sections. The foundryman may treat his iron with a small amount (0.5 to 2.5 kg/Mg, or 1 to 5 lb/ton) of a graphitizing alloy such as calcium-bearing ferrosilicon or other proprietary inoculant, which effectively decreases chill. Inoculation to achieve control of the tendency to chill usually does not result in significant changes in the composition or the physical properties of the iron, although it does produce changes in the mechanical properties.

Light sections (5 mm, or $\frac{3}{16}$ in.) usually cannot be cast in gray iron of higher than class 25. Class 30 iron can be cast in 6 mm ($\frac{1}{4}$ in.) sections. These values are different for different designs, depending on how the casting is made and gated.

The important thing to understand is that the cooling rate in the mold at the time of freezing determines whether the iron will be gray, white, or mottled. If the thin section is in the drag or near the gate, the flow of hot metal heats the mold, thereby decreasing the rate of cooling and enhancing the formation of the gray iron.

If chill is encountered, it is generally best to correct the trouble at its origin. It is usually uneconomical to anneal castings to remove chill because, in addition to heat treating for 2 h at 900 °C (1650 °F) for unalloyed irons, recleaning may be required for removing scale. Distortion beyond tolerance often occurs, and there are sacrifices in hardness and strength.

Adhering sand usually can be removed by effective cleaning, but sand present as the result of penetration of the iron into the mold wall is extremely difficult to blast clean. This is a foundry defect that is best corrected at the source. Slowing the speed of machining and increasing the rate of feed is the best approach to salvaging castings of this type. Carbide tools are better than high-speed tools for resisting the extreme abrasion.

Swells are most troublesome in operations such as broaching and in other setups tooled for high production. The additional metal often places an excessive load on the tool, which may chip or dull but not actually fail until some time after the troublesome parts have been machined. In highly automated machining centers, this casting defect can result in significant statistical variation in dimensions and high scrap rates.

Shifted castings are similar to swells in their action on cutting tools. Shifts or swells also may cause excessive tool loading if the locating points are affected. It is important to consider the positions of such locating points when designing the castings and also to avoid indiscriminate grinding of locating points in the foundry cleaning room.

Shrinks are not present but can be troublesome when encountered in operations such as drilling. For example, the drill may tend to drift from its intended path to follow the shrink, which offers less resistance to the drill. Sometimes a drill

may break because it encounters a region of higher hardness, which often is associated with an area of shrink. Cast iron is the easiest metal to cast without internal shrink. Eutectic freezing is accompanied by expansion due to the precipitation of low-density graphite, which aids in obtaining internal soundness.

Machinability rating is complex and is discussed in the article "Machinability of Steels" in this Volume. Criteria such as power per unit volume in unit time are of greatest importance in selecting a machine tool and the size of its motor. Machinability ratings based on tool life under standard test conditions are helpful but are not readily interpreted into the economics of machining.

One way to indicate the effect on machinability of changing from one grade of iron to another is shown in Table 15, which is based on an experiment in which metal was removed from four types of gray iron using single-point carbide tools. For each type of iron, cutting speed was varied until the removal of 3300 cm³ (200 in.³) of iron resulted in a 0.75 mm (0.030 in.) wear land on the tool. The values of cutting speed thus obtained serve as qualitative evaluations of machinability, but not as qualitative indices. Optimum cutting speeds, tool materials, cutting fluids, feeds, and finish requirements must be studied for any given machine tool setup. Tool life is an important factor, because the machine must be stopped to change tools and the tools must be resharpened. Progress has been made in decreasing both machine downtime for tool changes and resharpening cost by the use of solid carbide inserts or bits and by other means.

Table 15 Machinability of gray iron

Microstructure	ASTM class	Tensile strength		Hardness, HB	Cutting speed ^(a)	
		MPa	ksi		m/min	ft/min
Acicular iron	50	407	59	263	46	150
Fine pearlite, alloy	40	310	45	225	95	310

(a) Cutting speed at which removal of 3280 cm³ (200 in.³) produced 0.75 mm (0.030 in.) wear land on single-point carbide tools.

Annealing. The greatly improved machinability obtainable in gray iron by annealing has been advantageous to automotive and other industries for many years. Annealing is usually of the subcritical type, such as 1 h at 730 to 760 °C (1350 to 1400 °F). Some employ a cycle of heating to 785 to 815 °C (1450 to 1500 °F) and cooling at 22 °C/h (40 °F/h) to about 595 °C (1100 °F). These treatments graphitize the carbide in the pearlite and result in a ferritic matrix. Finding it uneconomical to graphitize primary carbide, most users try to avoid obtaining it. Annealing for improved machinability is most economical when the casting is small and the amount of machining is large.

The annealing treatments described result in sacrifices in hardness and strength. A typical class 35 iron will be downgraded to about class 20 in strength by this treatment. In applications in which wear resistance is important, such as cylinder blocks, gray iron is not annealed because of the unsatisfactory performance obtained with a ferritic matrix.

Table 16 and Fig. 15 show the changes in hardness, strength, and structure of class 35 gray iron obtained by annealing.

Table 16 Effect of annealing on hardness and strength of class 35 gray iron

Wear

Gray iron is used widely for machine components that must resist wear. Different types of iron, however, exhibit great differences in wear characteristics. These differences do not correlate with the commonly measured properties of the iron.

In the discussion that follows, the general conclusions are related to metal-to-metal wear during sliding contact under conditions of normal lubrication. Although most of the supporting illustrations are for engine cylinders, the results have wider applicability.

The published data on gray iron wear are somewhat inconsistent; accelerated-wear tests often do not correlate with field service experience, nor does field experience in one application necessarily agree with that in another application. In many applications, properties of the surface are at least as important as properties of the metal; for instance, wear resistance may frequently be enhanced by lapping the wear areas. Relative hardness between mating parts also may be important to optimum wear resistance. Frequently, a hardness difference no greater than 10 points on the Brinell scale is considered optimum.

For components in sliding contact, such as engine cylinders, valve guides, and latheways, the recognized types of wear are cutting wear, abrasive wear, adhesive wear, and corrosive wear. In well-designed machinery, wear proceeds slowly and consists of combinations of very mild forms of these four types of wear. The predominant characteristic of this so-called normal wear is the development of a glazed surface during break-in. The primary objective in any wear application is to establish conditions that produce and maintain this glaze. A secondary objective is to minimize normal wear.

Cutting wear is caused by the mechanical removal of surface metal as a result of surface roughness and is similar to the action of a file. It usually occurs during the breaking in of new parts.

Abrasive wear is caused by the cutting action or loose, abrasive particles that get between the contacting faces and act like a lapping compound. Under some circumstances, abrasive particles embedded in one or both of the contacting faces can produce a similar action.

Adhesive wear is caused by metal-to-metal contact, resultant welding, and the breaking of those welds. When this happens on a large scale (a process known as galling), the metal is smeared, and severe surface damage results. Even in properly operating equipment, some wear occurs by adhesion on a microscopic scale. An intermediate form of adhesive wear called scuffing is less destructive than galling, but still results in an abnormally high rate of metal removal. In all probability, accelerated-wear tests between clean surfaces (with or without the presence of a lubricant) are predominantly tests of galling or scuffing.

Corrosive wear is a special type of wear that combines abrasion or adhesion with the chemical action of the environment. In engine cylinders, it is caused by condensed acidic products of combustion during low-temperature operation. Usually this kind of wear cannot be corrected by modifications in ordinary types of gray iron.

Resistance to Scuffing

Assuming reasonable design and operating conditions that minimize cutting and abrasive wear, scuffing or mild galling is the abnormal wear condition most likely to defeat the objective of obtaining and maintaining a glazed surface due to normal wear. Several alloy combinations with widely varied microstructures were tested by Shuck (Ref 11). A brake shoe type of specimen was held against a rotating gray iron drum for 1 h, after which both specimen and drum were checked for weight loss. The conditions of this test indicate that wear was caused primarily by adhesion (scuffing), although cutting wear may have had a contributing effect. The tests covered almost all conceivable microstructures and a wide variety of compositions having hardnesses below 300 HB. The conclusions, which basically agreed with other less comprehensive investigations, were:

- Microstructure determines wearing characteristics
- As the graphite structure becomes coarser and tends toward type A, scuffing decreases
- Interdendritic type D graphite and its associated ferrite give very poor results
- Secondary ferrite associated with random type A graphite is less damaging than that associated with type D
- Pearlitic, acicular, or tempered martensitic structures in the same hardness range are equal in wear resistance
- For a given type of graphite, as the matrix becomes more pearlitic and harder, wear resistance increases

These results were substantiated in scuff tests of cylinder sleeves in a diesel engine. The engine, equipped with the test sleeves, was operated at constant speed, and the horsepower was increased by increments above normal until scuffing occurred. The scuffing horsepower was expressed in a ratio with normal horsepower.

Effect of Graphite Structure. To eliminate differences in matrix, four types of gray iron were hardened and tempered at 205 °C (400 °F) to produce a uniform martensitic matrix. The data in Table 17 show that the greater the amount and flake size of graphite, the greater the resistance to scuffing. The changes in casting method in tests 3 and 4 caused no significant change in scuffing. The iron in test 5 is one used formerly in high-performance brake drums to give maximum resistance to scoring.

Table 17 Effect of graphite structure on resistance to scuffing

Test No.	Type of graphite ^(a)	Total carbon, %	Resistance to scuffing ^(b)
1	None (5150 steel)	...	<1 ^(c)
2	100% type D, centrifugally cast	3.25 (average)	1.11

3	Type A, size 4 to 6, some type B, centrifugally cast	3.28	1.33
4	Same as 3 except cast in sand mold	3.35 (average)	1.30
5	Type A, size 3 to 4, some type C, sand cast	4.00	>1.45^(d)

(a) Different chemical compositions were tested in two of the four types of iron. See Table 19 for compositions. Matrix of all specimens was tempered martensite.

(b) Expressed as ratio: horsepower to produce scuffing divided by normal horsepower.

(c) All the steel sleeves scuffed below normal horsepower.

(d) Maximum available engine horsepower produced no scuffing.

Effect of Matrix Structure. Similar tests, in which the graphite was type D and the matrix was varied, gave the results shown in Table 18. The combination of type D graphite and ferrite in test 1 is especially poor even though the rest of the structure is pearlite. Pearlitic type A iron with small amounts of free ferrite gave ratios greater than 1.33 in the same tests, showing that the results obtained in test 1 are peculiar to the combination of type D graphite and ferrite. When type D graphite occurs in as-cast irons, it is usually associated with ferrite. Consequently, foundry practices that avoid the formation of type D graphite should be adopted when producing castings for wear applications.

Table 18 Effect of matrix microstructure on resistance to scuffing

Test No.	Microstructure of matrix	Hardness	Resistance to scuffing ^(a)
1	Pearlite, with ferrite occurring in graphitic areas	196-227 HB	<1 ^(b)
2	Martensite tempered at 205 °C (400 °F)	53-56 HRC	1.06
3	Martensite tempered at 425 °C (800 °F)	44-47 HRC	1.22
4	Martensite tempered at 510 °C (950 °F)	39-41 HRC	1.39

(a) Expressed as a ratio: horsepower to produce scuffing divided by normal horsepower.

(b) All sleeves scuffed below normal operating range.

Several investigators have noted similar, apparently inconsistent, results, which can be summarized as follows: increasing hardness from 160 to 260 HB increases resistance to scuffing; however, further increasing hardness above 260 HB decreases resistance to scuffing, even in heat-treated structures.

These tests, along with those of Ref 11, apparently apply only to scuffing and not to normal wear. As indicated in the section "Resistance to Normal Wear," wear resistance is different for different modes of wear.

Other investigators have observed that a fine network of steadite (iron phosphide-iron carbide eutectic) increases scuff resistance, while massive carbide reduces it.

Effect of Chemical Composition. The diesel cylinder scuff tests for evaluating the effect of graphite used five different compositions from five foundries for tests 3 and 4 and three compositions from two foundries for test 2. Despite the variations in source and in composition (Table 19), all fine type A irons performed nearly alike in the scuff tests. Similarly, the three type D materials performed essentially the same. No other composition was checked with coarse type A graphite. To cover the subject of scuffing more completely, other factors were evaluated during the cylinder sleeve tests. They help to clarify some of the additional controversial aspects of wear.

(b) Typical composition.

(c) Corresponds to tests 3 and 4 in Table 17.

(d) Corresponds to test 5 in Table 17

Surface finish effects were determined by running similar tests on cylinder sleeves with honed finishes of 0.75 and 2.3 μm (30 and 90 $\mu\text{in.}$) rms. In each, the sleeves were made from type D graphite iron, hardened, and tempered at 205 °C (400 °F).

The coarser finish gave about 20% greater scuff resistance; however, this effect was lost if the finish became finer under normal operating conditions. The loss of scuff resistance by the smoothing effect of normal wear may account for some of the failures that occur in certain applications after break-in has apparently been successful.

Other important factors affecting scuff resistance are the material and finish of the mating part and the type of lubricant used.

Resistance to Normal Wear

The scuff resistance described above should not be used as a basis for selecting a material that must resist normal wear. Resistance to normal wear, like resistance to scuffing, is affected by both graphite form and matrix microstructure (and possibly by the composition of the iron), but in a different manner.

Some of the same sleeve materials involved in the scuff tests were operated under conditions that produced normal wear with very little evidence of scuffing. Tests were run for approximately 1000 h using chromium-plated compression rings on the pistons. All sleeves were hardened and tempered at 205 °C (400 °F). Results are given in Table 20. Each of the three sleeve materials performed best when different types of wear were considered: the material in No. 2 test gave the lowest ring wear; in No. 4, the lowest sleeve wear; and in No. 5, the greatest resistance to scuffing. Thus, the choice of optimum sleeve material is a compromise.

Table 20 Effect of type of graphite on wear resistance

Test No. ^(a)	Type of graphite	Total carbon, %	Resistance to scuffing ^(a)	Sleeve wear, mm/1000 h (in./1000 h)	Ring wear (gap increase), mm/1000 h (in./1000 h)
2	100% type D	3.10-3.40	1.11	0.075 (0.003)	0.050 (0.002)
4	Type A, size 4 to 6, some type B	3.25-3.50	1.30	0.050 (0.002)	0.685 (0.027)
5	Type A, size 3 to 4, some type C	4.00	1.45	0.090 (0.0035)	2.15 (0.085)

(a) See Table 17

Effect of Graphite Structure. It was concluded from the above tests that graphite produces a surface-roughening effect, which accounts for both the greater scuff resistance and the higher ring wear as the size and quantity of graphite are increased. In testing type D graphite sleeves with the rougher finish previously mentioned, improved scuff resistance was also obtained, but at the expense of greater ring wear, apparently from cutting. The larger quantity of graphite in test 5 leaves less load-carrying metal surface, and greater normal wear on the sleeve is the logical result.

The relatively high sleeve wear in test 2 was probably caused by slight scuffing, which gave high wear values for some sleeves tested, presumably because of the low safety margin of scuff resistance in this type of iron. Surprisingly, this mild scuffing did not seem to affect the chromium-plated rings, which apparently wore less severely in the presence of fine graphite. The plain gray iron oil-control rings, however, wore more in test 2 than in test 4. The principal effect of graphite on wear resistance is the elimination of scuffing, and when graphite is present in greater quantity and size than required for this purpose, it will reduce resistance to normal wear unnecessarily.

Effect of Matrix Microstructure. Gray iron is used for wear resistance in both the as-cast and hardened conditions. To show the effects of some of the matrix variations on wear resistance, comparable engine wear tests were made on seven types of gray iron cylinders, all of which apparently wore in a normal manner. These data are summarized in Tables 21 and 22.

Table 21 Effect of matrix microstructure on resistance of gray iron to normal wear

Iron ^(a)	No. of tests	Type and size of graphite	Matrix	Rate of wear	
				mm/1000 h	in./1000 h
A	28	A, size 3 to 4	Lamellar pearlite	0.14	0.0057
B	19	A, size 4	Lamellar pearlite plus phosphide	0.03	0.0012
C	4	A, size 5 to 6	Fine lamellar pearlite	0.022	0.0009

F	3.30-3.40	0.90-1.10	1.75-2.00	...	0.40-0.50	0.20 max	0.12 max	...
G	3.00-3.20	0.90-1.10	1.15-1.35	0.20 max	0.12 max	...

By present standards, hardening is the process that can produce the most significant improvement in resistance to normal wear. Although iron E in Table 21 showed exceptionally good wear properties, it was less resistant than the hardened iron G and at the same time could not be cast readily into the required shape. Thus, when evaluated on the basis of combined properties, the hardened iron G was twice as wear resistant as iron D, the as-cast iron that had the best combination of wear resistance and castability. From other extensive testing, it has been concluded that hardened iron has as much as five times more wear resistance than pearlitic as-cast iron of the same general composition (Ref 12).

Another significant advantage of hardening is that it greatly reduces variations in matrix microstructure and thus provides a superior iron of more dependable performance. In most applications such as valve guides, latheways, and various sliding members in machines and engines, satisfactory wear resistance is obtained with properly specified and controlled as-cast gray iron. Hardened iron is used to obtain maximum wear resistance in severe wearing applications such as high-speed diesel cylinder sleeves, camshafts, gears, and similar heavily loaded wearing surfaces.

For more information on the effects of composition and microstructure on the wear resistance of cast iron, specifically that of white and chilled iron, see the article "Alloy Cast Irons" in this Volume.

Elevated-Temperature Properties

The most demanding applications of gray irons at elevated temperatures are those in which dimensional accuracy is important. The effect of elevated temperatures on dimensional stability is discussed below.

Less rigorous applications at high temperatures are those in which a load is to be carried but in which appreciable distortion can be tolerated. In this case, the important properties include tensile strength, fatigue properties, and creep-rupture strength at elevated temperatures. Figures 13(b) and (c) show the effects of temperature on the fatigue limit and tensile strength of a gray iron. Figure 16 shows the creep rupture properties of gray iron with molybdenum (Fig. 16a) and with molybdenum and chromium (Fig. 16b). As the figure shows, creep rupture strength is improved with the addition of chromium and molybdenum.

Fig. 16 Influence of chromium and molybdenum on stress to produce rupture in 100 h in gray iron at various temperatures. (a) Unalloyed base iron. (b) 0.6% Cr alloyed base iron. Source: Ref 13

Dimensional Stability

Effect of Temperature. The dimensional stability of gray iron is degraded as temperature and exposure time increase. Dimensional stability at elevated temperatures is affected by factors such as growth, scaling, and creep rate.

Growth of the iron is the result of the breakdown of the pearlite to ferrite and graphite. To prevent this growth, alloying elements such as copper, molybdenum, chromium, tin, vanadium, and manganese must be added because they will stabilize the carbide structure. Examples of these effects are seen in Fig. 17. Alloying additions are generally recommended at temperatures above 400 °C (750 °F). Chromium and chromium-nickel-molybdenum additions are most effective in retarding growth.

Fig. 17 Growth of four gray iron alloys produced from the same base iron (3.3% C, 2.2% Si) and tested at 455 °C (850 °F) in air. Source: Ref 7, 14.

Scaling is another source of dimensional change. Table 23 gives the results of scaling tests. In general, differences in alloy content had only minor effects on scaling.

Table 23 Scaling of gray iron at elevated temperatures

Temperature exposure	Extent of scaling, mg/cm ²
11.5 years	
At 350 °C (660 °F)	4
At 400 °C (750 °F)	4
64 weeks	
At 450 °C (840 °F)	3-4.5
At 500 °C (930 °F)	6-16

Creep. A gray iron part that operates at elevated temperature will deform by creep if the load is great enough. Table 24, which gives the creep characteristics of several gray irons at 370 °C (700 °F) and at stresses ranging from 72 to 165 MPa

(10.5 to 24 ksi) suggests the usefulness of molybdenum additions for improving the creep properties of gray iron. Creep rupture properties are improved with additions of chromium and molybdenum (Fig. 16).

Table 24 Results of creep tests of gray iron at 370 °C (700 °F)

Iron composition, % ^(a)	Hardness, HB	Tensile strength		Creep stress		Deformation rate ^(b)

(b) In mm/m · h, or 10⁻³ in./in. · h.

(c) 0 to 500 h

If the part is to operate below 480 °C (895 °F), two sources of dimensional inaccuracy must be considered: residual stresses and machining practice.

Residual stresses are present in all castings in the as-cast condition and are caused by:

- Differences in cooling rate between sections of the same casting because of different cross sections or locations in the mold
- Resistance of the mold to contraction of the casting during cooling
- High-energy cleaning, such as with shot, which can induce compressive stresses

Residual stresses as high as 220 MPa (32 ksi) have been reported in gray iron wheels. Stresses of 170 MPa (25 ksi) have been observed in localized areas of other gray iron castings. Residual stresses in engine cylinder blocks have been measured as high as 130 MPa (19 ksi). Figure 18 shows two examples of residual stress in light castings, as determined with resistance strain gages.

Fig. 18 Location and magnitude of residual stresses in two gray iron castings

Only a small percentage of castings are stress relieved before machining, chiefly those requiring exceptional accuracy of dimensions or those with a combination of high or nonuniform stress associated with either low section stiffness or an abrupt change in section size. Castings of class 40, 50, and 60 iron are more likely to contain high residual stresses.

Figure 19 shows stress relief at seven temperatures between about 310 and 600 °C (600 and 1100 °F). The range from 480 to 600 °C (900 to 1100 °F) recommended. For best results, castings should be held at temperature 1 h or more and then cooled in the furnace to below 450 °C (850 °F). High-strength and alloy gray irons require temperatures approaching 600 °C (1100 °F).

Fig. 19 Stress relief of gray iron at various temperatures. Source: Ref 17

Machining Practice. In castings in the as-cast condition, residual tension and compression stresses are balanced, which makes the castings dimensionally stable at room temperature. However, when part of the surface is removed in machining, the balance of forces is altered, which can lead to distortion. If the casting is of relatively stiff section or has properly designed stiffness ribs, there may be no noticeable change in dimensions. Distortion will be most evident in castings of low stiffness from which a large volume of highly stressed metal has been removed.

Because the surface of a casting is often the principle site of residual stresses, a large proportion of the stress is relieved by rough machining, with consequent maximum distortion. If, before final machining, the casting is relocated carefully and properly supported in the machine tool fixtures, acceptable dimensional accuracy will usually be obtained in the finished piece.

In designing fixtures, it must be recognized that the usual gray iron (class 30) has a modulus of elasticity of about 97 GPa (14×10^6 psi), which means that deflection under tool bit loads will be approximately twice as great in a part made of this cast iron as in a steel part having the same section.

It is difficult to make general statements about the dimensional stability that can be achieved in a gray iron casting without stress relieving. However, it is well known that automotive engine blocks are taken directly from the foundry without stress relieving and are machined to tolerances of ± 0.005 mm (± 0.0002 in.) in parts such as crankshaft bearings, camshaft bearings, and cylinder bores. Therefore, if a casting is properly designed, is cast under controlled conditions, and is allowed to cool sufficiently in the mold before shakeout, and if proper machining practice is followed, extremely high dimensional stability can be obtained in many applications without stress relieving. On the other hand, it is frequently economical to stress relieve complex castings (other than engine blocks) that are produced in small quantities and that must be machined to precise dimensions.

Effect of Shakeout Practice

Shakeout practice may be influential in establishing the patterns of residual stresses in castings, because most residual stresses are basically caused by differences in cooling rate, and thus in contraction behavior, between light and heavy sections.

In addition to its effect on residual stress, shakeout practice may influence both microstructure and hardness of gray iron castings. If the iron is austenitic at the time the mold is dumped, higher hardness and residual stress may result. Many different microstructures may be obtained; the austenite in thin sections may transform in the mold, whereas in heavier sections, which cool more slowly, transformation may be delayed until air cooling after shakeout. In general, the effect of shakeout practice on hardness is negligible in unalloyed irons. Alloy irons are the most sensitive. However, the martensitic irons that contain enough alloying elements to reach full hardness with slow cooling in the mold will display little if any effect of shakeout practice.

Alloying to Modify As-Cast Properties

The term alloying as used here does not include inoculation because by definition the effect of inoculation on the mechanical properties of an iron is greater than can be explained by the change in chemical composition.

Strength and hardness, resistance to heat and oxidation, resistance to corrosion, electrical and magnetic characteristics, and section sensitivity can be changed by alloying, which can extend the application of gray iron into fields where costlier materials have traditionally been used.

There has also been considerable replacement of unalloyed gray iron by alloy iron to meet increased service demands and to provide increased safety factors.

The use of alloy iron often depends, in practice, on the relative production requirements in a given foundry. When the applications requiring alloy iron in a given plant are a small fraction of total production, manufacturing policy may dictate the use of unalloyed iron for all castings in order to achieve maximum uniformity of production practice. Continuous production of 450 to 1350 kg (1000 to 3000 lb) heats of alloy iron is usually needed for economical utilization.

Manganese, chromium, nickel, vanadium, and copper can also be used to strengthen cast irons. In many irons a combination of elements will provide the greatest increase in strength.

To develop resistance to the softening effect of heat and protect against oxidation, chromium is the most effective element. It stabilizes iron carbide and therefore prevents the breakdown of carbide at elevated temperatures; 1% Cr gives adequate protection against oxidation up to about 760 °C (1400 °F) in many applications. For temperatures above 760 °C (1400 °F), the chromium content should be greater than 15% for long-term protection against oxidation. This percentage of chromium suppresses the formation of graphite and makes the alloy solidify as white cast iron.

For corrosion resistance, chromium, copper, and silicon are effective. Additions of 0.2 to 1.0% Cr decrease the corrosion rate in seawater and weak acids. The corrosion resistance of iron to dilute acetic, sulfuric, and hydrochloric acids and to acid mine water can be increased by the addition of 0.25 to 1.0% Cu. For sulfur and acid corrosion, 15 to 30% Cr is effective. Silicon additions in the range of 14 to 15% give excellent corrosion resistance to sulfuric, nitric, and formic acids; however, both high-chromium and high-silicon irons are white, and the high-silicon irons are extremely brittle.

The electrical and magnetic properties of cast iron can be modified slightly by minor additions of alloying elements, but a major change in characteristics can be accomplished by the use of approximately 15% Ni or of nickel plus copper, which

results in an austenitic iron that is virtually nonmagnetic. The austenitic gray irons also have good resistance to oxidation and growth at temperatures up to about 800 °C (1500 °F).

Molybdenum is an effective alloying addition for retaining strength in heavy sections. It is normally added in amounts of 0.5 to 1.0%, but the low end of this range applies chiefly when molybdenum is added in combination with other elements. In the casting in thin sections, nickel is the most effective in combating the tendency to form chilled iron.

Base Irons. The selection of alloying elements to modify as-cast properties in gray iron depends to a large extent on the composition and method of manufacture of the base iron. For example, a foundry producing a base iron containing 2.3% Si and 3.4% total carbon for automotive castings might add 0.5 to 1.0% Cr if required to make heavier castings with the same hardness and strength as the normal castings. However, a foundry producing a base iron with 1.7% Si and 3.1% C for a heavy casting would add 0.5 to 0.8% Si to decrease hardness and chill when pouring this iron in light castings.

Depending on the strength desired in the final iron, the carbon equivalent of the base iron may vary from approximately 4.4% for weak irons to 3.0% for high-strength irons. The method of producing the base iron will affect mechanical properties and the alloy additions to be made, because factors such as type and percentage of raw materials in the metal charge, amount of superheat, and cooling rate of the iron after pouring all affect the properties. The base iron used for alloying will vary considerably from foundry to foundry, as will the alloying elements selected to give the desired mechanical properties. However, parts produced from different base irons and alloy additions can have the same properties and performance in service.

Heat Treatment

Gray iron, like steel, can be hardened by rapid cooling or quenching from a suitable elevated temperature. The quenched iron may be tempered by reheating in the range from 150 to 650 °C (300 to 1200 °F) to increase toughness and relieve stresses. The quenching medium may be water, oil, hot salt, or air, depending on composition and section size. Heating may be done in a furnace for hardening throughout the cross section, or it may be localized as by induction or flame so that only the volume heated above the transformation temperature is hardened. In the range of composition of the most commonly used unalloyed gray iron castings, that is, about 1.8 to 2.5% Si and 3.0 to 3.5% TC, the transformation range is about 760 to 845 °C (1400 to 1550 °F). The higher temperature must be exceeded in order to harden the iron during quenching. The proper temperature for hardening depends primarily on silicon content, not carbon content; silicon raises the critical temperature.

During the heating of unalloyed gray iron for hardening, graphitization of the matrix frequently begins as the temperature approaches 600 to 650 °C (1100 to 1200 °F) and may be entirely completed at a temperature of 730 to 760 °C (1350 to 1400 °F). This latter range is used for maximum softening. The changes in combined carbon content and hardness that occur upon heating and quenching of both alloyed and unalloyed gray iron are shown in Table 25.

Table 25 Hardness of quenched samples of gray iron

Condition	Plain cast iron		Cr-Ni-Mo cast iron	
	Combined carbon, %	Hardness, HB	Combined carbon, %	Hardness, HB
As-cast	0.69	217	0.70	2.55
After quenching from, °C (°F)				
650 (1200)	0.54	207	0.65	2.50
675 (1250)	0.38	187	0.63	241

705 (1300)	0.09	170	0.59	229
730 (1350)	0.09	143	0.47	217
760 (1400)	nil	137	0.45	197
790 (1450)	0.05	143	0.42	207
815 (1500)	0.47	269	0.60	444
845 (1550)	0.59	444	0.69	514
870 (1600)	0.67	477	0.76	601

Note: Specimens were 30.5 mm diam bars, 51 mm long (1.2 in. diam bars, 2 in. long) quenched in oil from temperatures shown.

Source: Ref 18

Ordinarily, gray iron is furnace hardened from a temperature of 860 to 870 °C (1575 to 1600 °F). This results in a combined carbon content of about 0.7% and a hardness of about 45 to 52 HRC (415 to 514 HB) in the as-quenched condition. The actual hardness of the martensitic matrix is 62 to 67 HRC, but the presence of graphite causes a lower indicated hardness (Table 14). Temperatures much above this are not advisable because the as-quenched hardness will be reduced by retained austenite.

Oil is the usual quenching medium for through hardening. Quenching in water may be too drastic and may cause cracking and distortion unless the castings are massive and uniform in cross section. Hot oil and hot salt are sometimes used as quenching media to minimize distortion and quench cracking. Water is often used for quenching with flame or induction hardening if only the outer surface is to be hardened.

Hardenability of unalloyed gray iron is about equal to that of low-alloy steel. Hardenability can be measured using the standard end-quench hardenability test employed for steels. The hardenability of cast iron is increased by the addition of chromium, molybdenum, or nickel. Gray iron can be made air hardenable by the addition of the proper amounts of these elements. Some typical data on the hardenability of plain and alloy irons are shown in Table 26. Compositions of the irons are listed in Table 27.

Mechanical Properties. As-quenched gray iron is brittle. Tempering after quenching improves strength and toughness but decreases hardness. A temperature of about 370 °C (700 °F) is required before the toughness (impact strength) approaches the as-cast level. The tensile strength after tempering may be from 35 to 45% greater than the strength of the as-cast iron. Changes in properties brought about by quenching and tempering are shown in Fig. 20.

Fig. 20 Changes in mechanical properties of gray iron as a function of tempering temperature

Heat treatment is not ordinarily used commercially to increase the overall strength of gray iron castings, because the strength of the as-cast metal can be increased at less cost by reducing the silicon and total carbon contents or by adding alloying elements. When gray iron is quenched and tempered, it usually is done to increase resistance to wear and abrasion by increasing hardness. A structure consisting of graphite embedded in a hard martensitic matrix is produced by heat treatment. Localized heat treatment such as flame or induction hardening can be used in some applications in which

alloy iron or chilled iron has traditionally been used, often with a savings in cost. Heat treatment can be used when chilling is not feasible, as with complicated shapes or large castings, or when close tolerances that can be attained only by machining are required. Heat treatment extends the field of application of gray iron as an engineering material.

The hardness of quenched and tempered gray iron measured with either a Brinell or Rockwell C tester is a composite hardness that superimposes the effects of graphite type, distribution, and size on the hardness of the metal matrix. The true hardness of the matrix, measured with a microhardness test, is generally from 8 to 10 HRC points higher than the hardness indicated by the conventional Rockwell C test. This is shown in Fig. 21, which compares composite hardness with matrix hardness. The composite hardness was obtained by conventional Rockwell testing; the matrix hardness was measured with a Vickers indenter and a 200 g load, and the values were converted to equivalent Rockwell hardness. The hardness of the matrix and the change in matrix hardness with tempering temperature are about the same as in an alloy steel containing approximately 0.7% C.

Fig. 21 Effect of tempering temperature on the hardness of quenched gray iron (3.30% C, 2.35% Si)

After tempering at 370 °C (700 °F) for maximum toughness, the hardness of the metal matrix is still about 50 HRC. Where toughness is not required and a tempering temperature of 150 to 260 °C (300 to 500 °F) is acceptable, the matrix hardness is equivalent to 55 to 60 HRC. High matrix hardness and the presence of graphite result in a surface with good wear resistance for some applications, for instance, farm implement gears, sprockets, diesel cylinder liners, and automotive camshafts.

Dimensional changes resulting from the hardening of gray iron are quite uniform and predictable if the prior structure and composition are uniform. Such dimensional changes can be allowed for in machining before heat treatment.

Complex shapes or nonuniform sections may be distorted as a result of the relief of residual casting stresses or a differential rate of cooling and hardening during quenching, or both. The former condition can be minimized by stress relieving at about 565 to 590 °C (1050 to 1100 °F) before machining. The latter can be minimized by either marquenching or austempering; both of these processes are used for cylinder liners where out-of-roundness must be held to a minimum. Through hardening is employed for gears, sprockets, hub bearings, and clutches.

Localized Hardening. In parts requiring only localized areas of hardness, conventional induction hardening or flame hardening may be used.

For flame hardening, it is generally desirable to alloy the iron with small amounts of either chromium or molybdenum to stabilize the iron carbide and thus prevent graphitization. Also, adequate localized hardening is enhanced when the structure contains little or no free ferrite prior to hardening. Compared to a pearlitic matrix, it may take from two to four times as long at temperature to condition a ferritic matrix for hardening. Even though the diffusion of carbon into austenite from the adjacent graphite is quite rapid, the attainment of a carbon concentration that can produce full hardness may require 1 to 10 min (or more) for a previously ferritic matrix, depending on ferrite composition, austenitizing temperature, and graphite distribution and spacing.

Water may be used as the quenching medium when the depth of hardening is shallow and the part is progressively heated and quenched. When only small areas are being hardened, the parts may be dropped into an oil quench. Localized hardening has been used for camshafts, gears, sprockets, and cylinder liners.

Physical Properties

Patternmakers' rules (shrink rules) allow 1% linear contraction upon solidification and cooling of gray iron. (The comparable allowances for other cast ferrous metals are 0% for annealed ductile iron, 0.7% for ascast ductile iron, $1\frac{1}{2}$ to 2% for white iron, 2% for cast carbon steel, and $2\frac{1}{2}$ % for cast alloy steel.) Often, in practice this allowance is inaccurate necessitating more exact evaluation of the effects of mass, composition, shape, mold, and core. Generally, contraction is less with an increase in mass and in gray irons increases with increasing tensile strength.

Three contraction phenomena are exhibited during the cooling of a cast iron from the molten state to room temperature: in the liquid, contraction of about 2.8% from 1425 °C (2600 °F) to the liquidus at about 1200 °C (2200 °F); contraction during solidification; and subsequent to solidification, contraction of about 3.0% from 1150 °C (2100 °F) to room temperature.

Shrinkage in volume during solidification ranges from negative shrinkage in "soft" irons to +1.94% in an iron containing about 0.90% combined carbon. The white irons undergo 4.0 to 5.5% contraction in volume within the same temperature range.

Coefficient of thermal expansion of gray irons is about $13\text{ }\mu\text{m/m} \cdot ^\circ\text{C}$ ($7.2\text{ }\mu\text{in./in.} \cdot ^\circ\text{F}$) in the range from 0 to 500 °C (32 to 930 °F) and about $10.5\text{ }\mu\text{m/m} \cdot ^\circ\text{C}$ ($5.8\text{ }\mu\text{in./in.} \cdot ^\circ\text{F}$) in the range from 0 to 100 °C (32 to 212 °F). The coefficient of thermal expansion is highly dependent on the matrix structure. The coefficients of thermal expansion of ferritic and martensitic irons are slightly higher than those of pearlitic irons.

For the temperature range from 1070 °C (1960 °F) to room temperature, the coefficient of thermal expansion varies from 9.2 to $16.9\text{ }\mu\text{m/m} \cdot ^\circ\text{C}$ (5.1 to $9.4\text{ }\mu\text{in./in.} \cdot ^\circ\text{F}$). At about room temperature, the commonly used figure of $10\text{ }\mu\text{m/m} \cdot ^\circ\text{C}$ ($5.5\text{ }\mu\text{in./in.} \cdot ^\circ\text{F}$) is accurate enough for moderate changes in temperature.

Density of gray irons at room temperature varies from about 6.95 Mg/m^3 for open-grained high-carbon irons to 7.35 Mg/m^3 for close-grained low-carbon irons. The density of white iron is about 7.70 Mg/m^3 .

Thermal conductivity of gray iron is approximately $46\text{ W/m} \cdot \text{K}$. See Table 28.

Table 28 Coefficients of thermal expansion for various gray irons compared with several steels and other irons

Electrical and Magnetic Properties. The resistivity of gray iron, compared with that of other ferrous metals, is relatively high, apparently because of the amounts and distribution of the graphite. Increases in total carbon content and in silicon content increase resistivity.

The magnetic properties of gray iron may vary within wide limits, ranging from those of irons having low permeability and high coercive force (suitable for permanent magnets) to those of irons having high permeability, low coercive force, and low hysteresis loss (suitable for electrical machinery).

The highest magnetic induction and permeability are found in annealed white irons, such as malleable cast iron. Flake graphite, as in gray iron, does not affect hysteresis loss, but prevents the attainment of high magnetic induction by causing small demagnetizing forces.

Damping capacity is the capability of a material to quell vibrations and to dissipate the energy as heat, or simply the relative capability to stop vibrations or ringing. Because gray iron possesses high damping capacity, it is well suited for bases and supports, as well as for moving parts. It reduces or eliminates parasitic vibration. The noise level of a machine operating on a gray iron base is materially reduced. High damping capacity is especially desirable in structures and parts in which vibration can cause stresses in excess of those that result from direct loading. Table 29 compares the relative damping capacity of gray iron with the relative damping capacities of other common structural alloys.

Table 29 Relative damping capacities of some common structural alloys

Material	Relative damping capacity
Gray iron, coarse flake	100-500
Gray iron, fine flake	20-100
Malleable iron	8-15
Ductile iron	5-20
Pure iron	5
Eutectoid steel	4
White iron	2-4
Aluminum	0.4

Ductile Iron

Revised by Lyle R. Jenkins, Ductile Iron Society; and R.D. Forrest, Pechiney Electrometallurgie, Division Fonderie

Introduction

DUCTILE CAST IRON, previously known as nodular iron or spheroidal-graphite (SG) cast iron (the international term is ductile iron), is cast iron in which the graphite is present as tiny spheres (nodules) (see Fig. 1). In ductile iron, eutectic graphite separates from the molten iron during solidification in a manner similar to that in which eutectic graphite separates in gray cast iron. However, because of additives introduced in the molten iron before casting, the graphite grows as spheres, rather than as flakes of any of the forms characteristic of gray iron. Cast iron containing spheroidal graphite is much stronger and has higher elongation than gray iron or malleable iron. It may be considered as a natural composite in which the spheroidal graphite imparts unique properties to ductile iron.

Fig. 1 Microstructures of ductile iron. (a) As-cast ferritic. (b) As-cast pearlitic; hardness, 255 HB. (c) Ferritic, annealed 3 h at 700 °C (1290 °F). (d) Pearlitic ductile iron oil quenched and tempered to 255 HB. All etched in 2% nital. 100×

The relatively high strength and toughness of ductile iron give it an advantage over gray iron or malleable iron in many structural applications. Also, because ductile iron does not require heat treatment to produce graphite nodules (as does malleable iron to produce temper-carbon nodules), it can compete with malleable iron even though it requires a treatment and inoculation process. The mold yield is normally higher than with malleable iron. Ductile iron can be produced to x-ray standards because porosity stays in the thermal center. Malleable iron cannot tolerate porosity because voids migrate to the surface of hot spots such as fillets and appears as cracks.

Typically, the composition of unalloyed ductile iron differs from that of gray iron or malleable iron (Table 1). The raw materials used for ductile iron must be of higher purity. All cast irons can be melted in cupolas, electric arc furnaces, or induction furnaces. Ductile iron, as a liquid, has high fluidity, excellent castability, but high surface tension. The sands and molding equipment used for ductile iron must provide rigid molds of high density and good heat transfer.

Table 1 Composition of selected cast irons

Type	Composition, %										
	TC ^(a)	Mn	Si	Cr	Ni	Mo	Cu	P	S	Ce	Mg
Gray iron	3.25-3.50	0.50-0.90	1.80-2.30	0.05-0.45	0.05-0.20	0.05-0.10	0.15-0.40	0.12 max	0.15 max

(a) TC, total carbon.

(b) Optional

The formation of graphite during solidification causes an attendant increase in volume, which can counteract the loss in volume due to the liquid-to-solid phase change in the metallic constituent. Ductile iron castings typically require only minimal use of risers (reservoirs in the mold that feed molten metal into the mold cavity to compensate for liquid contraction during cooling and solidification). Gray irons often do not require risers to ensure shrinkage-free castings. On the other hand, steels and malleable iron generally require heavy risering. Thus, the mold yield of ductile iron castings (the ratio of the weight of usable castings to the weight of metal poured) is much higher than that of either steel castings or malleable iron castings, but not as high as that of gray iron. There are some cases of ductile iron castings being made without risers.

Often designers must compensate for the shrinkage of cast iron during both solidification and subsequent cooling to room temperature by making patterns with dimensions larger than those desired in the finished castings. Typically, ductile iron requires less compensation than any other cast ferrous metal. The allowances in patternmaker rules (shrink rules) are usually:

Type of cast metal	Shrinkage allowance, %
Ductile iron	0-0.7
Gray iron	1.0
Malleable iron	1.0
Austenitic alloy iron	1.3-1.5

White iron	2.0
Carbon steel	2.0
Alloy steel	2.5

Shrinkage allowance can vary somewhat from the percentages given above, and often different percentages must be used for different directions in one casting because of the influence of the solidification pattern on the amount of contraction that takes place in different directions. Shrinkage is volumetric, and the ratio of dimensions to volume influences each dimension. As ductile iron approaches a condition of shrinkage porosity, the graphite nodules tend to become aligned and can result in lower fatigue strength.

Most ductile iron castings are used as-cast, but in some foundries, some castings are heat treated before being shipped. Heat treatment varies according to the desired effect on properties. Any heat treatment, with the exception of austempering, reduces fatigue properties. Holding at subcritical (705 °C, or 1300 °F) temperature for no more than 4 h improves fracture resistance. Heating castings above 790 °C (1450 °F) followed by fast cooling (oil quench or air quench) significantly reduces fatigue strength and above-room-temperature fracture resistance. Ferritizing by heating to 900 °C (1650 °F) and slow cooling also reduces fatigue strength and above-room-temperature fracture resistance. Heating to above the critical temperature also reduces the combined carbon content of quenched and tempered microstructures and produces lower tensile strength and wear resistance than the same hardness produced as-cast. Some castings may be given hardening treatments (either localized surface or through hardened) that produce bainitic or martensitic matrices.

In recent years, considerable interest has been shown in the property improvements obtained in ductile iron by austempering heat treatments. Austempered ductile iron (ADI) has a matrix that is a combination of acicular (bainitic) ferrite and stabilized austenite. As the matrix structure is progressively varied from ferrite to ferrite plus pearlite to pearlite to bainite and finally to martensite, hardness, strength, and wear resistance increase, but impact resistance, ductility, and machinability decrease. Overall, however, this structure results in an exceptional combination of strength, ductility, and wear resistance. Table 2 shows the ASTM standards for austempered ductile iron. Some of the applications for austempered ductile iron include:

- Gears (including side and timing gears)
- Wear-resistant parts
- High-fatigue strength applications
- High-impact strength applications
- Automotive crankshafts
- Chain sprockets
- Refrigeration compressor crankshafts
- Universal joints
- Chain links
- Dolly wheels

1600-1300	1600	...	1300	...	(b)	(b)	...	444-555

(a) Unnotched Charpy bars tested at 72 ± 7 °F (22 ± 4 °C). The values in the table are a minimum for the average of the highest three test values of four tested samples.

(b) Elongation and impact requirements are not specified. Although grades 200-155-1, 1400-1100-1, 230-185, 1600-1300 are primarily used for gear and wear resistance applications, grades 200-155-1 and 1400-1100-1 have applications where some sacrifice in wear resistance is acceptable in order to provide a limited amount of ductility and toughness.

(c) Hardness is not mandatory and is shown for information only.

Ductile iron can be alloyed with small amounts of nickel, molybdenum, or copper to improve its strength and hardenability. The addition of molybdenum is done with caution because of the tendency for intercellular segregation. Larger amounts of silicon, chromium, nickel, or copper can be added for improved resistance to corrosion, oxidation, or abrasion, or for high-temperature applications. The high-alloy ductile irons are covered in the article "Alloy Cast Irons" in this Volume. Representative microstructures of both unalloyed and alloyed ductile irons can be found in *Metallography and Microstructures*, Volume 9 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Ductile Iron

Specifications

Most of the specifications for standard grades of ductile iron are based on properties; that is, strength and/or hardness is specified for each grade of ductile iron, and composition is either loosely specified or made subordinate to mechanical properties. Tables 3 and 4 list compositions, properties, and typical applications for most of the ductile irons that are defined by current standard specifications (except for the high-nickel, corrosion-resistant, and heat-resistant irons defined in ASTM A 439). As shown in Table 4, the ASTM system for designating the grade of ductile iron incorporates the numbers indicating tensile strength in ksi, yield strength in ksi, and elongation in percent. This system makes it easy to specify nonstandard grades that meet the general requirements of ASTM A 536. For example, grade 80-60-03 (80 ksi, or 552 MPa, minimum tensile strength, 60 ksi, or 414 MPa, yield strength, and 3% elongation) is widely used in applications for which relatively high ductility is not important. Grades 65-45-12 and 60-40-18 are used in areas requiring high ductility and impact resistance. Grades 60-42-10 and 70-50-05 are for special applications such as annealed pipe or as-cast pipe fittings. Grades other than those listed in ASTM A 536 or mentioned above can be made to the general requirements of A 536, but with the mechanical properties specified by mutual agreement between purchaser and producer.

Table 3 Compositions and general uses for standard grades of ductile iron

Specification No.	Grade or class	UNC	TC ^(b)	Typical composition, %				Description	General uses
				Si	Mn	P	S		
ASTM A 395; ASME SA395	60-40-18	F32800	3.00 min	2.50 max ^(c)	...	0.08 max	...	Ferritic; annealed	Pressure-containing parts for use at elevated temperatures

Note: For compositions, descriptions, and uses, see Table 2.

(a) Measured at a predetermined location on the casting.

(b) Determined using a standard specimen taken from a separately cast test block, as set forth in the applicable specification.

(c) Range specified by mutual agreement between producer and purchaser.

(d) Value must be compatible with minimum hardness specified for production castings.

The Society of Automotive Engineers (SAE) uses a method of specifying iron for castings produced in larger quantities that is based on the microstructure and Brinell hardness of the metal in the castings themselves. Both ASTM and SAE specifications are standards for tensile properties and hardness. The tensile properties are quasi-static and may not indicate the dynamic properties, such as impact or fatigue strength.

The International System of grade designation (ISO 1083) uses the tensile strength value, in MPa, and elongation percentage. Table 5 shows the property requirements of the ASTM, SAE, and ISO specifications. No standard for austempered ductile iron has yet been approved, although tentative specifications have been proposed, as shown in Table 6 and Fig. 2.

Ductile Iron

Revised by Lyle R. Jenkins, Ductile Iron Society; and R.D. Forrest, Pechiney Electrometallurgie, Division Fonderie

Ductile Iron Applications

Ductile iron castings are used for many structural applications, particularly those requiring strength and toughness combined with good machinability and low cost. The selection of casting, instead of mechanical fabrication, as the production process often allows the designer to:

- Use to best advantage the combination of properties that is unique to ductile iron
- Combine several functions (or component shapes) in a single integrated configuration
- Realize the economic advantages inherent in casting, which is the simplest and most direct of the various production processes

Casting is like forming with a homogenous liquid that can flow smoothly into a wide variety of thicknesses, shapes, and contours. The material is consistent piece to piece, day after day because it is made from a pattern that has very low wear and dimensional change and that is produced to a specification. The microstructure is uniform, with neither directional flow lines nor variations from weld junctions or heat-affected zones. Any porosity is predictable and remains in the thermal center. Machining costs are low because there is less material to remove and to dispose of, castings are easier to machine, and cutting tools are subjected to less tool wear.

Properties unique to ductile iron include the ease of heat treating because the free carbon in the matrix can be redissolved to any desired level for hardness and strength control. Free carbon can be selectively hardened by flame, induction, laser, or electron beam. A 650 °C (1200 °F) anneal for 3 h can produce high toughness at low temperatures. Ductile iron can be austempered to high tensile strength, high fatigue strength, high toughness, and excellent wear resistance. Second, lower density makes ductile iron weigh 10% less than steel for the same section size. Third, the graphite content provides damping properties for quiet running gears. Also, the low coefficient of friction produces more efficient gear boxes. Furthermore, ductile iron has less tendency to gear seizures from the loss of lubricant.

Experience has proved that ductile iron works in applications in which experience and handbook data say it should not. This is because data in the literature do not describe the true properties of ductile iron, whereas it is very easy to make a prototype casting and try it in the field. This practice has resulted in very large cost savings and superior performance compared to the material it replaces. A ductile iron casting can be poured and shipped the same day. As-cast ductile iron castings are consistent in dimensions and weight because there is no distortion or growth due to heat treatment.

The automotive and agricultural industries are the major users of ductile iron castings. Almost 3×10^6 tonnes (2.9×10^6 t, or 3.2×10^6 tons) of ductile iron castings were produced in the United States in 1988, the majority of components being for automotive applications. Because of economic advantages and high reliability, ductile iron is used for such critical automotive parts as crankshafts, front wheel spindle supports, complex shapes of steering knuckles, disk brake calipers, engine connecting rods, idler arms, wheel hubs, truck axles, suspension system parts, power transmission yokes, high-temperature applications for turbo housings and manifolds, and high-security valves for many various applications. It can be rolled or spun into a desired shape or coined to an exact dimension.

The cast iron pipe industry is another major user of ductile iron.

Austempered ductile iron has resulted in many new applications for ductile iron. It is a high-strength, wear-resistant, heat-treated material. It has more than double the strength of conventional ductile iron for a given level of ductility (Fig. 3). Austempered ductile iron gets its remarkable properties from a special austempering heat treatment. The resultant strength properties can be varied by controlling the heat treat cycle, which is described in this article in the section "Heat Treatment." In the austempering process, good-quality ductile iron can be transformed into a superior engineering material. It cannot transform poor-quality iron into a good-quality material.

Ductile Iron

Revised by Lyle R. Jenkins, Ductile Iron Society; and R.D. Forrest, Pechiney Electrometallurgie, Division Fonderie

Metallurgical Control in Ductile Iron Production

Greater metallurgical and process control is required in the production of ductile iron than in the production of other cast irons. Frequent chemical, mechanical, and metallurgical testing is needed to ensure that the required quality is maintained and that specifications are met.

The manufacture of high-quality ductile iron begins with the careful selection of charge materials that will give a relatively pure cast iron, free of the undesirable residual elements sometimes found in other cast irons. Carbon, manganese, silicon, phosphorus, and sulfur must be held at specified levels. Magnesium, cerium, and certain other elements must be controlled to attain the desired graphite shape and offset the deleterious effects of elements such as antimony, lead, titanium, tellurium, bismuth, and zirconium, which interfere with the nodulizing process and must be either eliminated or restricted to very low concentrations and neutralized by additions of cerium and/or rare earth elements. Alloying elements such as chromium, nickel, molybdenum, copper, vanadium, and boron act as carbide formers, as pearlite stabilizers, or as ferrite promoters. Alloys are controlled to the extent needed to obtain the required mechanical properties and/or microstructure in the critical section(s) of the casting.

A reduction of the sulfur content in the base iron to below 0.02% is necessary prior to the nodulizing process (except with certain pure magnesium treatment processes); this can be accomplished by basic melting alone or by desulfurization of the base metal (more commonly used today) before the magnesium-nodulizing alloy is added. If base iron sulfur is not reduced, excessive amounts of costly nodulizing alloys are required, and greater amounts of slag and dross are generated.

Graphite Shape and Distribution

There are three major types of nodulizing agents, all of which contain magnesium:

- Unalloyed magnesium metal
- Magnesium-containing ferrosilicons
- Nickel-base nodulizers

Unalloyed magnesium metal has been added to molten iron as wire, ingots, or pellets; as briquets in combination with sponge iron; as pellets in combination with granular lime; or in the cellular pores of metallurgical coke.

Magnesium-Containing Alloys. The method of introducing magnesium alloys has varied from an open-ladle or covered-ladle method (in which the alloy is placed at the bottom of a ladle that has a height-to-diameter ratio of between 2:1 and 1.5:1 and iron is poured rapidly over the alloy) to a plunging method, or to a pressure-container method in which unalloyed magnesium is placed inside a container holding molten iron and the container is rotated so that the iron flows over the magnesium. The magnesium metal can also be plunged to the bottom of the iron in a pressure ladle. In all cases, magnesium is vaporized, and the vapors travel through the molten iron, lowering the sulfur content and promoting the formation of spheroidal graphite.

Nickel-Base Nodulizers. A nickel alloy with 14 to 16% Mg can be added to the ladle during filling or by plunging. The reaction is spectacular, but not violent, and a very consistent recovery is obtained. A disadvantage lies in the accompanying increase in nickel and the cost of the alloy. Other nickel alloys containing much lower magnesium contents (down to 4%) have also been used and involve a much quieter reaction.

Ferrosilicon-based inoculant is usually added to the nodulized iron when it is transferred to the pouring ladle. This produces a high nodule count and a matrix of preferred microstructure. With the proper control of shakeout time and temperature, certain ductile iron castings can meet grade specifications as-cast, without further heat treatment. Hardness uniformity is attained by the addition of pearlite-forming elements such as copper.

Testing and Inspection

Various tests are used to control the processing of ductile iron. The first is the analysis of raw materials and of the molten metal, both before and after the nodulizing treatment. Rapid thermal-arrest methods are used to confirm carbon, silicon, and carbon equivalence (CE) in the molten iron. Carbon equivalence is not used to allow broader carbon or silicon ranges; these elements still have definite individual ranges that must be held. Silicon content is determined by thermoelectric, spectrometric, and wet chemical analysis. Chill tests are used to control nucleation, indicate a carbide-forming tendency, and alert production control in the event that silicon has been omitted. The temperature of the molten iron in the furnace is measured by immersion thermocouple prior to the nodulizing process. It is also measured in the pouring ladle. Weight control is exercised for the amount of metal being treated, the amount of alloys being added, and the amount of metal being inoculated. Time control is used to ensure that all treated metal is poured within a given period, beginning with the nodulization treatment and including the inoculation. Minimum pouring temperatures are established, and any iron that does not meet the minimum standard is not allowed to be poured into molds.

A standard test coupon for microscopic examination must be poured from each batch of metal with the same iron that is poured into the last mold. This coupon is described in ASTM A 395. One ear of the test coupon is removed and polished to reveal graphite shape and distribution, as well as matrix structure. These characteristics are evaluated by comparison with standard ASTM/AFS photomicrographs, and acceptance or rejection of castings is based on this comparison.

Tensile-test specimens are machined from separately cast keel blocks, Y blocks, or modified keel blocks, as described in ASTM A 395. If the terms of purchase require tensile specimens to be taken from castings, the part drawing must identify the area of the casting and the size of the test specimen. A tensile specimen should never be cut from the centerline of a round section, but rather from the midradius or as near the surface as possible. These terms must be mutually acceptable to producer and purchaser.

The hardness testing of production castings is also used to evaluate conformance to specified properties. Some standard specifications, such as SAE J434b, relate strength and hardness, as shown in Fig. 4. A comparison of tensile properties with hardness of as-cast ductile iron and pearlitic malleable iron is shown in Fig. 5. This shows that the tensile strength of as-cast ductile iron is significantly higher than that of pearlitic malleable iron at all hardnesses. The elongation is higher than that of oil-quenched pearlitic malleable iron. Air-quenched pearlitic malleable iron has a higher elongation than oil-quenched iron because the air-quenched iron has a ferrite ring around the temper-carbon nodules. As oil-quenched pearlitic malleable iron is tempered to a lower hardness, the elongation increases. This is also true in the case of fatigue strength, as shown in Fig. 6, in which the endurance limit of 217 HB oil-quenched pearlitic malleable iron is higher than that of 255 HB. The yield strength of as-cast ductile iron is lower than oil-quenched and tempered pearlitic malleable iron when the hardness is above 217 HB. This is because the ferrite ring around the graphite nodules shows yielding at 0.2% offset. The yield strength of as-cast ductile iron can be increased to as high or higher than the yield strength of oil-quenched and tempered pearlitic malleable iron, and the hardness can be as high, but the tensile strength and elongation will be significantly lower. The fatigue strength will be lower, too, as shown in Fig. 6. When ductile iron is heated to 900 °C (1650 °F), oil quenched, and tempered, the peak of combined carbon between graphite nodules is reduced and spread out to the nodules, thereby eliminating the ring of ferrite. A loss in wear resistance is experienced, because of the lower combined carbon content at the same hardness as the as-cast iron. The producer and the purchaser must agree on a suitable location, usually indicated on the part drawing, for hardness testing. The preferred method for ductile iron hardness testing is the Brinell method. Surface preparation must be done carefully, and the casting must be cool before it is indented with the 10-mm tungsten carbide ball in a regularly calibrated machine. A proving ring is used to check the machine load of 30 kN (3000 kgf), and a stage micrometer is used to check the calibration of the Brinell scope. A hardness value may be listed as a Brinell indentation diameter (BID) or Brinell hardness number (HB). Other methods of measuring hardness with small indentors, such as the Rockwell method, have variations due to the small area of indentation that contains soft graphite nodules. Electromagnetic techniques may be used for the hardness testing of as-cast simple shapes, such as crankshafts (see the article "Electromagnetic Techniques for Residual Stress Measurements" in *Nondestructive Evaluation and Quality Control*, Volume 17 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*).

Verification of graphite nodularity in castings can be obtained using ultrasonic methods that measure the velocity of sound through the section being tested. Several companies have installed on-line systems to verify nodularity, particularly in automotive components such as brake calipers and steering knuckles. Nondestructive inspection of ductile iron castings, including ultrasonic verification of nodularity, is described in the articles "Castings" and "Ultrasonic Inspection" in *Casting*, Volume 17 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. Sonic decay and resonant-frequency methods are also used.

Heat Treatment

The heat treatment of ductile iron castings produces a significant difference in mechanical properties from as-cast ductile iron. The beneficial result of heat treating ductile iron is the increase in impact resistance if the temperature is restricted to 705 °C (1300 °F) and the time is limited to 4 h. Most other forms of heat treatment, with the exception of austempering, cause a loss in fatigue strength, wear resistance, and room-temperature impact resistance, compared to as-cast ductile iron of the same hardness.

Stress Relieving. Occasionally ductile iron castings of large or nonuniform cross section are stress relieved at 540 to 595 °C (1000 to 1100 °F), which reduces warping and distortion during subsequent machining. Mechanical properties are reduced if the temperature selected causes a reduction in hardness.

Annealing. Full ferritizing annealing is used to remove carbides or stabilized pearlite in order to meet ASTM grade 60-40-18 requirements. This heat treatment usually involves heating to 900 °C (1650 °F), holding at temperature long enough to dissolve the carbides (possibly up to 3 h), then slow cooling at 85 °C/h (150 °F/h) to 705 °C (1300 °F) and still-air cooling to room temperature. This hypercritical anneal lowers the nil-ductility

transition temperature (NDTT) to improve low-temperature fracture resistance, but results in a lower upper-shelf impact energy and a significant reduction in fatigue strength. In some cases, it may reduce the tensile and/or yield strength to levels below ASTM standards. The nil-ductility transition temperature is the temperature at which the material transforms from a partially ductile to a fully brittle material with no ductility.

Subcritical annealing produces either ASTM grade 60-40-18 or grade 65-45-12 for applications requiring high toughness and ductility. It produces greater low-temperature fracture resistance than as-cast ductile iron used for greater low-temperature fracture resistance than as-cast ductile iron used for steering knuckle applications.

Normalizing, quenching, and tempering produces ASTM grade 100-70-03, which is widely used for applications requiring good strength, wear resistance, and good response to localized hardening. Castings are heated to 900 °C (1650 °F), held at temperature for 3 h (allowing 1 h/25 mm, or 1 h/in., of section size to reach temperature), then air blasted or oil quenched, followed by tempering at 540 °C (1000 °F) or up to 675 °C (1250 °F), depending on the required final hardness. The yield strength may be higher than as-cast iron for the same hardness, but the ultimate tensile strength and elongation will be lower. The wear resistance at 228 HB (4.1 BID) will be lower than as-cast iron of the same hardness. At 255 HB (3.8 BID), the short-time fatigue strength (350,000 cycles) of D7003 oil quenched and tempered (OQT) may appear to be slightly higher, but the long life (10^6 cycles) will be significantly lower than that of as-cast iron. At 217 HB (4.1 BID), both the short-time and long-time fatigue strength are significantly lower. This is shown in Fig. 5. The impact resistance of oil-quenched and tempered ductile iron is lower than that of as-cast iron at 50 °C (125 °F) and above, but higher at temperatures under 45 °C (110 °F) (see Fig. 7).

Fig. 7 Dynamic tear energy versus temperature for as-cast and heat-treated ductile irons. Specimen size: 190 mm ($7\frac{1}{2}$ in.) long, 130 mm ($5\frac{1}{8}$ in.) wide, and 41 mm ($1\frac{5}{8}$ in.) thick; 13 mm ($\frac{1}{2}$ in.) notch depth. Source: Ref 2

Martensitic ductile iron ASTM grade 120-90-02 is produced by heating to 900 °C (1650 °F), holding to homogenize, quenching in agitated oil, and tempering at 510 to 565 °C (950 to 1050 °F).

Austempered ductile iron requires a two-stage heat treatment. The first stage, austenitizing, requires heating to and holding at about 900 °C (1650 °F). This is followed by the second stage, which requires quenching and isothermally holding at the required austempering temperature, usually in a salt bath.

Typically, austempered ductile iron is produced by heating the castings in a controlled atmosphere to an austenitizing temperature between 815 to 925 °C (1500 to 1700 °F). The castings are held at temperature for a

long enough time to saturate the austenite with carbon in solution. The castings are then cooled at a rate sufficiently fast enough to avoid the formation of pearlite and other high-temperature transformation products to the appropriate transformation temperature (this may vary from 230 to 400 °C, or 450 to 750 °F, depending on the hardness and strength required). The castings are held at the selected transformation temperature for a long enough time to produce the desired properties. Austempered ductile iron transformed in the 370 °C (700 °F) range exhibits high ductility and impact resistance at a tensile strength of about 1035 MPa (150 ksi). When transformed at 260 °C (500 °F), it exhibits wear resistance comparable to case hardened steel and tensile strength in excess of 1380 MPa (200 ksi).

Thus, the selection of the austempering temperature and time of holding is critical. In general, austempering in the 240 to 270 °C (465 to 520 °F) range provides a component that has maximum strength but limited ductility, while austempering in the 360 to 380 °C (680 to 715 °F) range yields a component that exhibits maximum ductility and toughness, in combination with relatively high strength, albeit lower than that obtained at the lower austempering temperature (see Fig. 8). Figure 9 compares the strength and ductility of as-cast nodular irons and of nodular irons subjected to the heat treatments discussed in this section.

Fig. 8 Relationship between austempering temperature and the strength and ductility of a 1.5Ni-0.3Mo alloyed ductile iron. Austenitizing temperature was 900 °C (1650 °F). Source: Ref 3

Fig. 9 Strength and ductility ranges of as-cast and heat-treated nodular irons. Source: Ref 4

Surface Hardening

Ductile iron may be surface hardened to as high as 60 HRC which may have a microhardness of 62 HRC because the cone indenter averages the soft graphite nodules with the matrix hardness resulting in a lower reading than the actual metallic components of the matrix. The hardened zone produces a highly wear-resistant surface layer backed up by a core of tougher metal. Flame or induction methods can be used to heat the surface layer to about 900 °C (1650 °F) for a few seconds, after which the heated surface is quenched in a spray of water (which often contains a few percent of a water-soluble quenching aid). Surface hardening is most successful when the matrix is fully pearlitic and thus ASTM grades 100-7-03 and 120-90-02 respond best. However, as-cast hardnesses as low as 217 HB (4.1 BID) can be successfully surface hardened. Laser and electron-beam methods are also used for surface hardening.

Mechanical Properties

Most of the standard specifications for ductile iron require minimum strength and ductility, as determined by the use of separately cast, standard ASTM test bars described in ASTM A 395. The various specification limits have been established by the evaluation of the results from thousands of these test bars. The properties of test bars are useful approximations of the properties of finished castings. Test bar properties also make it possible to compare the metal from many different batches without having to account for the variations due to differences in the shapes being cast or in the production practices used in different foundries.

Test bars are machined from keel blocks, Y blocks, or modified keel blocks (see ASTM A 395 for details and dimensions). These test blocks are designed for ideal feeding from heavy molten metal heads over the mold and for controlled cooling at optimum rates. In practice, these characteristics may not be economically feasible or may be impossible to achieve because of the configuration of the casting. As a result, the properties of actual production castings may differ from those of test bars cast from the same heat of molten metal, a fact that is sometimes overlooked. Test bar properties are the most informative when their relationships to the properties of production castings have been previously established by the testing of bars machined from castings, by the selective overloading of castings, by stress analysis, or by field testing. Test bars cast to near testing dimensions may be attached to the casting and removed for machining and testing. Dynamic properties such as impact resistance and fatigue strength may be tested by casting dynamic tear and reverse-bending paddle bar specimens. Figure 10 shows the brittle fracture appearance of a dynamic tear specimen.

Fig. 10 Fractograph showing the brittle fracture of a ductile iron dynamic tear specimen. 355×

Effect of Composition. The properties of ductile iron depend first on composition. Composition should be uniform within each casting and among all castings poured from the same melt. Many elements influence

casting properties, but those of greatest importance are the elements that exert a powerful influence on matrix structure or on the shape and distribution of graphite nodules.

Carbon influences the fluidity of the molten iron and the shrinkage characteristics of the cast metal. Excess carbon not in solution, but in suspension, reduces fluidity. The volume of graphite is 3.5 times the volume of iron. As ductile iron solidifies, the carbon in solution precipitates out as graphite and causes an expansion of the iron, which can offset the shrinkage of the iron as it cools from liquid to solid. The amount of carbon needed to offset shrinkage and porosity is indicated in the following formula:

$$\% C + \frac{1}{7} \% Si \geq 3.9\% \quad (\text{Eq 1})$$

Carbon contents greater than this amount begin to decrease fatigue strength and impact strength before the effect is noticed on tensile strength. The size and the number of graphite nodules formed during solidification are influenced by the amount of carbon, the number of graphite nuclei, and the choice of inoculation practice. Normal graphite-containing ductile iron has 10% less weight than steel of the same section size. The graphite also provides lubricity for sliding friction, and the low coefficient of friction permits more efficiently running gears, which, furthermore, will not seize if a loss of lubricant is experienced in service. The graphite also produces ADI gears that are silent in operation. Graphite in the structure can provide good machinability of a ferritic material and then be available to redissolve into solution by heat treating to produce high strength and wear resistance.

The relationship between carbon content and silicon content in terms of the carbon equivalent, CE, is

$$CE = \% C + \frac{Si\%}{3} \quad (\text{Eq 2})$$

Figure 11 is a plot of the carbon equivalent versus the volume of feed metal required.

Fig. 11 Plot of carbon equivalent versus ductile iron feed metal requirement. Source: Ref 5

A chemical analysis for carbon content should be done prior to any formation of graphite. After graphite formation, the ability to obtain an accurate carbon content is limited because of the loss of carbon in sample preparation or, in some cases, because of segregation.

Silicon (Ref 6) is a powerful graphitizing agent. Within the normal composition limits, increasing amounts of silicon promote structures that have progressively greater amounts of ferrite; furthermore, silicon contributes to the solution strengthening and hardness of ferrite. Increasing the amount of ferrite reduces the yield strength and tensile strength, but increases the elongation and impact strength. The ferrite envelope surrounding the graphite nodule in pearlitic ductile iron reduces the indicated yield strength, but increases elongation, impact strength, and fatigue strength. Silicon reduces the impact strength of ferritic ductile iron both as-cast and subcritically annealed. To provide maximum resistance to fracture from room temperature down to -40 °C (-40 °F), silicon must be kept below 2.75% if the phosphorus content is below 0.02%. If the phosphorus content is 0.05%, the silicon content should be limited to 2.55%. High-temperature applications such as turbocharger housings require silicon contents from 3.75 to 4.25% and molybdenum contents up to 0.70%. This combination provides high-temperature oxidation resistance and dimensional stability. Even higher silicon contents are used for abrasion resistance.

Manganese (Ref 7). Among the alloying elements commonly used to improve the mechanical properties of ductile iron, manganese acts as a pearlite stabilizer and increases strength, but reduces ductility and machinability. It also promotes segregation to the cell boundaries and must be limited when making austempered ductile iron.

Nickel (Ref 7) is frequently used to increase strength by promoting the formation of fine pearlite and to increase hardenability, especially for surface-hardening applications or for producing austempered ductile iron.

Copper (Ref 7) is used as a pearlite former for high strength with good toughness and machinability.

Molybdenum (Ref 7) is used to stabilize the structure at elevated temperatures. It is also used to add hardenability to heavy sections in producing austempered ductile iron. The amount must be controlled because of the tendency of molybdenum to segregate to the cell boundaries as stable carbides.

Effect of Graphite Shape. The presence of graphite in ductile cast iron in the shape of spheroidal nodules instead of sharp flakes such as those found in gray cast iron is caused by the addition of magnesium (or magnesium and cerium) to the molten iron, resulting in a fivefold to sevenfold increase in the strength of the cast metal. Shapes that are intermediate between a true nodular form (such as ASTM type 1, shown in Fig. 12) and a flake form (such as ASTM type VII, also shown in Fig. 12) yield mechanical properties that are inferior to those of ductile iron with a true nodular graphite. The size and uniformity of distribution of graphite nodules also influence properties, but to a lesser degree than graphite shape. Small, numerous nodules are usually accompanied by high tensile properties and tend to reduce the likelihood of the formation of chilled iron in thin sections or at edges. An optimum nodule density exists. Excessive nodules may weaken a casting to such a degree that it may not withstand the rigors of its intended application. Each material must be evaluated for its specific application.

VII ^(c)	I	Flake graphite

(a) As defined in ASTM A 247.

(b) As defined in ISO/R 945-1969 (E).

(c) Divided into five subtypes: uniform flakes; rosette grouping: superimposed flake size; interdendritic, random orientation; and interdendritic, preferred orientation

Fig. 12 Seven graphite shapes used to classify cast irons

A ductile iron composition can be converted to a compacted graphite iron composition. Minor alterations in composition produce a controlled microstructure consisting of more than 5% spheroidal and less than 20% spheroidal graphite, with the remainder of the graphite being a compacted, blunt, vermicular shape. This then becomes compacted graphite (CG) iron, which has lower strength than standard ductile iron and higher strength than gray iron, but which has better thermal transfer characteristics and less tendency for porosity than standard ductile iron.

Effect of Section Size. The variable chiefly affected by section size is the cooling rate. It, in turn, affects both the size of the graphite nodules and the microstructure of the matrix. The heavier the section, the more slowly it cools, and therefore the larger and fewer are the graphite nodules that form during solidification. When casting ductile iron in sections greater than about 64 mm ($2\frac{1}{2}$ in.), there is a possibility of producing centerline or inverse chill in the last section to solidify. This is usually controlled by inoculation techniques.

The structure of the matrix is essentially determined by the cooling rate through the eutectoid temperature range, although the specific effects of cooling rate are modified by the presence of alloying elements, as discussed previously in the section "Effect of Composition." Slow cooling rates prevalent in heavy sections promote the transformation to ferrite. If a pearlitic matrix is desired, pearlite formers (such as copper) are added to the molten iron. It is important that castings be allowed sufficient cooling time in the mold to allow the lamellar pearlite to be tempered in order to break up the plates partially and be rendered machinable at hardnesses up to 321 HB (3.40 BID). Insufficient cooling time may produce very fine pearlite, which reduces machinability. As-cast ductile iron anneals itself in the mold. Without a pearlite former, castings with variations in section thickness will have variations in hardness. Bainite and martensite are not found in as-cast structures because they are formed by heat treatment. Rapid cooling of thin sections may produce acicular structures, which are usually some form of combined carbon (carbides).

Bainitic ferrite and retained austenite are the main matrix constituents in austempered ductile iron. In order to minimize the harmful effects of segregation in medium-and thick-section ADI castings, the graphite nodule count must be maintained as high as possible, ideally at a level greater than 150 nodules/mm² (9.7×10^4 nodules/in.²).

Tensile Properties. The tensile properties of one heat of ductile iron heat treated to strength levels approximately equivalent to four standard ductile irons are given in Table 7. These values are not necessarily the average property values that can be expected for metal produced as-cast to the indicated grades. As-cast tensile and elongation values are higher than heat treated values; however, the yield strength values may be lower. Within each grade, strength and ductility vary somewhat with hardness, as shown in Fig. 4. In some instances, the ranges of expected strength and ductility overlap those for the next higher or lower grade.

Table 7 Average mechanical properties of ductile irons heat treated to various strength levels

Determined for a single heat of ductile iron, heat treated to approximate standard grades. Properties were obtained using test bars machined from 25 mm (1 in.) keel blocks.

-----------	-----	-----	-------	--------------------	---------------------	-----	---------------------------	---------------------------	-----

(a) 0.2% offset.

(b) 0.0375% offset.

(c) Calculated from tensile modulus and Poisson's ratio in tension

As shown in Table 7, the modulus of elasticity in tension lies in the range of 162 to 170 GPa (23.5×10^6 to 24.5×10^6 psi) and does not vary greatly with grade. This value in tension should not be used in design for cantilever or three-point beam or torsion loading because the deflection is greater, and a value of 142 GPa (20.5×10^6 psi) should be used. The values of tensile modulus shown in Table 7 were determined using standard 12.83 mm (0.505 in.) diam tensile bars, with strain gages affixed to the reduced section (gage length).

Compressive Properties. The 0.20% offset yield strength of ductile iron in compression is generally reported to be 1.0 to 1.2 times the 0.2% offset yield strength in tension. The compressive properties shown in Table 7 were determined using specimens from the same single heat of ductile iron described in the section above.

Torsional Properties. Few data are available on the ultimate shear strength of ductile iron because it is very difficult to obtain accurate shear data on materials that exhibit some ductility. It is generally agreed that the ultimate shear strength of ductile cast iron is about 0.9 to 1.0 times the ultimate tensile strength. Table 7 gives data for shear strength and for 0.0375% offset yield strength in torsion for a single heat of ductile iron heat treated to strength levels approximately equivalent to those of four standard ductile irons.

Damping Capacity. The average damping capacity of ductile iron in the hardness range of 156 to 241 HB is about 6.6 times that of SAE 1018 and about 0.12 times that of ASTM class 30 gray cast iron. These data were obtained from resonant-frequency measurements:

Material	Log decay $\times 10^{-4}$
Ductile iron	8.316 ^(a)
SAE 1018 steel	1.31 ^(b) 1.23 ^(c)
Gray iron, class 30	68.67 ^(a)

(a) Mean value.

(b) Longitudinal direction.

(c) Transverse
direction

Austenitic ductile iron has a lower damping capacity than unalloyed ferritic ductile iron.

Impact Properties. Dynamic tear energy data for ferritic ductile iron are shown in Fig. 13. This figure compares the effect of heat treatment. Subcritical anneal was 3 h at 700 °C (1290 °F). Full ferritization was obtained by heating to 955 °C (1750 °F) and slow cooling in the same manner as for the ferritic malleable iron heat treatment. This data shows that ferritizing at temperatures above the critical temperature results in lower upper-shelf energy. It also reduces the fatigue strength of ductile iron, compared to a subcritical anneal. Figure 7 shows that heating to 900 °C (1650 °F) and then oil quenching and tempering reduces the upper-shelf energy, but raises the low-temperature energy to fracture.

Fig. 13 Dynamic tear energy versus temperature for four ferritic cast irons. Specimen size: 190 mm ($7\frac{1}{2}$ in.) long, 130 mm ($5\frac{1}{8}$ in.) wide, and 41 mm ($1\frac{5}{8}$ in.) thick; 13 mm ($\frac{1}{2}$ in.) notch depth. Source: Ref 2

Data from a comprehensive study of the impact properties of ductile iron are shown in Fig. 14. These data show that increasing pearlite decreases impact energy. Figure 15 shows that increasing silicon reduces impact energy at room temperature for ferritic ductile iron. Figure 16 shows that increasing phosphorus reduces impact energy and raises the nil-ductility transition temperature. The transition temperature is significantly affected by phosphorus and/or silicon content, but is affected little by other elements present within the normal variations in composition.

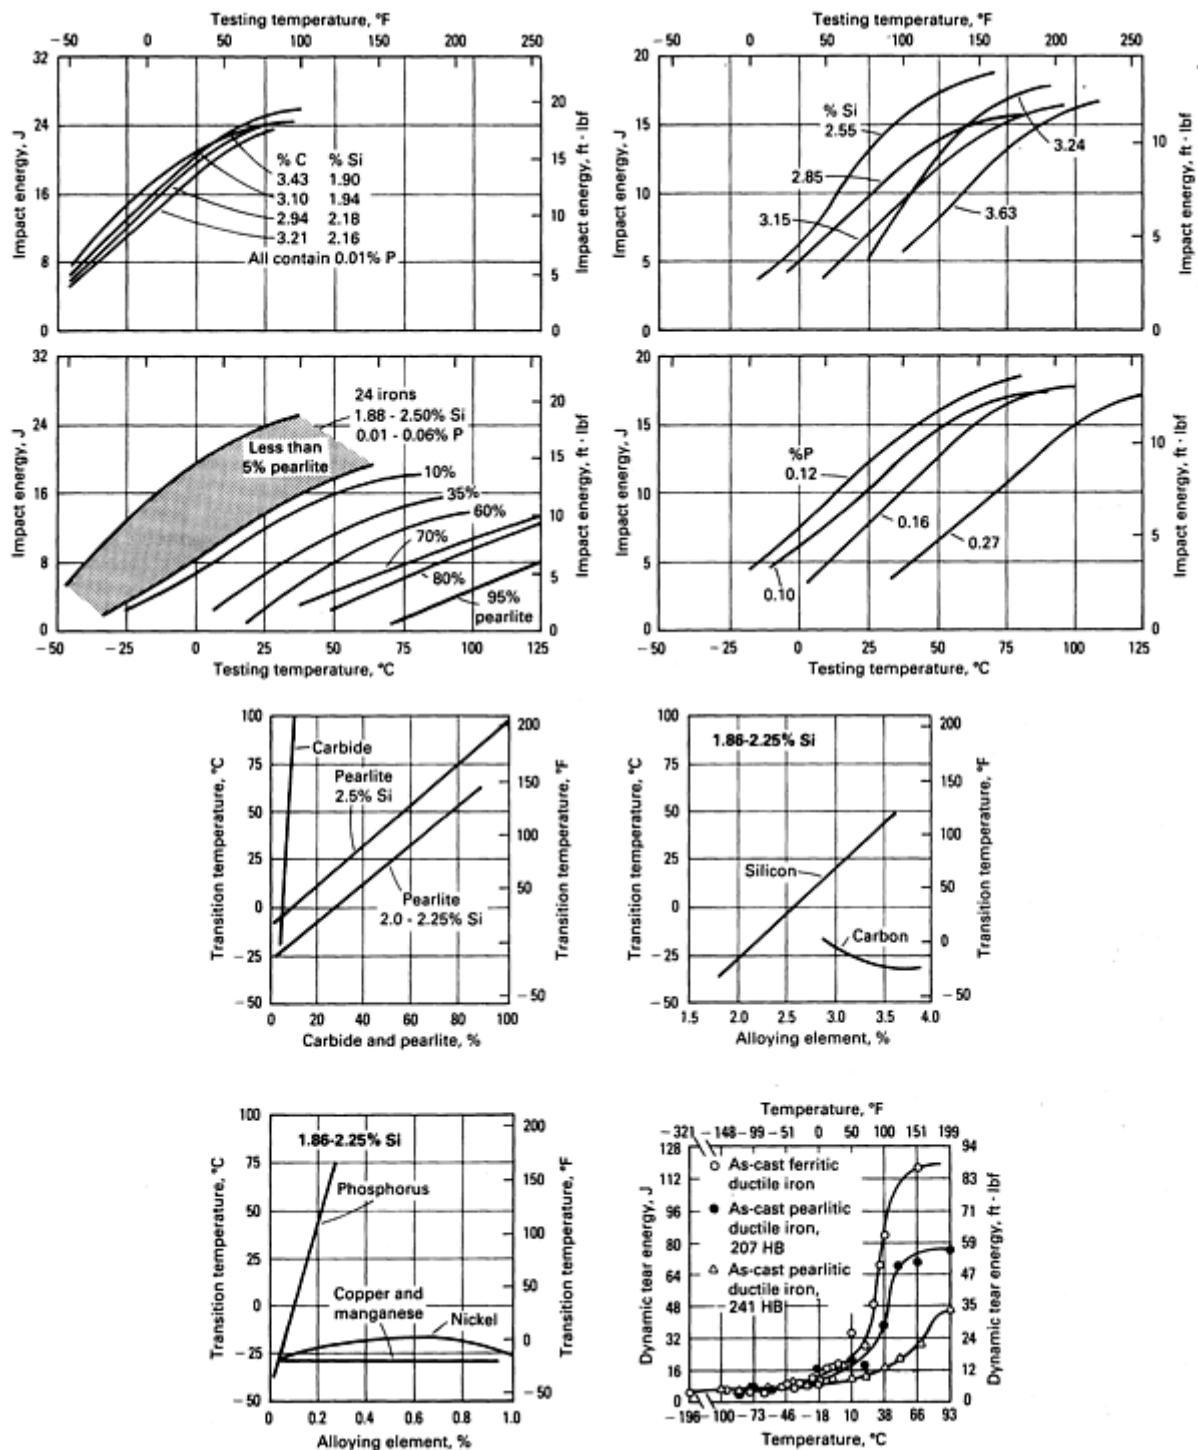

Fig. 14 Effect of composition and microstructure on Charpy V-notch impact behavior of ductile iron. Specimen size: 190 mm ($7\frac{1}{2}$ in.) long, 130 mm ($5\frac{1}{8}$ in.) wide, and 41 mm ($1\frac{5}{8}$ in.) thick; 13 mm ($\frac{1}{2}$ in.) notch depth. Fig. 16 Dynamic tear energy versus temperature to show effect of increasing phosphorus content in ferritic ductile irons. Specimen size: 190 mm ($7\frac{1}{2}$ in.) long, 130 mm ($5\frac{1}{8}$ in.) wide, and 41 mm ($1\frac{5}{8}$ in.) thick; 13 mm ($\frac{1}{2}$ in.) notch depth. Source: Ref 2

The effects of various heat treatments on Charpy V-notch impact energy are shown in Fig. 17 for a ductile iron alloyed with about 0.75% Ni. Curve F shows that austempering heat treatment not only improves elongation at high strength, but also produces the highest room-temperature impact energy of any of the conventional heat treatments, with the exception of surface-hardened as-cast ductile iron, curve A, with a hardness of 207 HB.

Fracture Toughness. Certain lower-strength grades of ductile iron do not fracture in a brittle manner when tested under nominal plane-strain conditions in a standard fracture toughness test. This behavior is contrary to the basic tenets of fracture mechanics and has been attributed to localized deformation in the ferrite envelope surrounding each graphite nodule. In the low-strength ductile irons, plane-strain conditions are established only at temperatures low enough to embrittle the ferrite. Otherwise, an increase in the size of the fracture toughness test specimens does not provide the degree of mechanical constraint necessary to obtain a valid measurement of K_{Ic} .

Selected values of fracture toughness are given in Table 8. These values were determined using compact tension specimens 21 mm (0.83 in.) in width. All tests were made in accordance with ASTM E 399. The data given in Table 8 are for ductile iron with a nodule shape approximately corresponding to 50% ASTM type I. In this same study, cast iron with a graphite shape similar to that in ASTM type IV (vermicular graphite) exhibited significantly lower fracture toughness, although a lower ferrite content and the absence of a ferrite ring around each graphite particle were considered to be of far greater significance than the lack of nodularity.

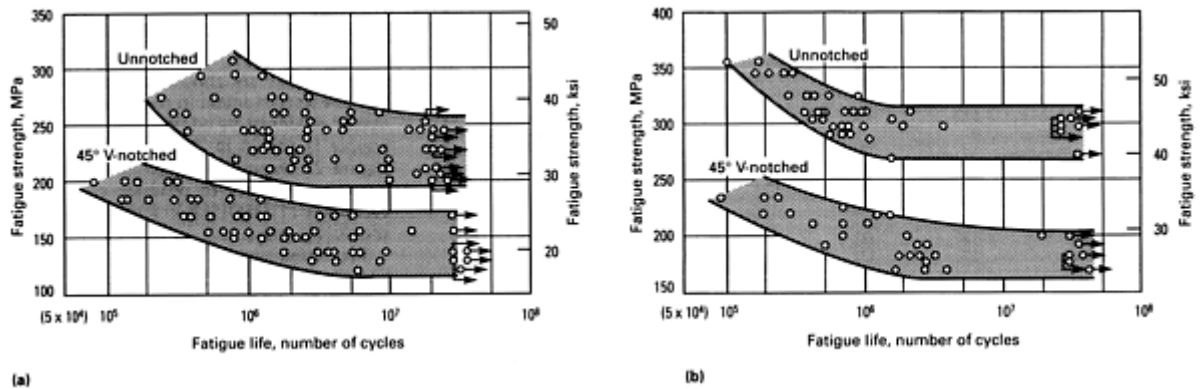

Table 8 Fracture toughness of ductile iron

Type of iron	Condition	Ultimate tensile strength		Yield strength		Elongation, %	K_{Ic} , MPa · m ^{0.5} (ksi · in. ^{1/2}) at

(a) Estimated.

Fatigue Strength. Figure 6 shows fatigue strength curves for pearlitic ductile iron of various grades and heat treatments compared with those of malleable iron and one grade of cast steel. The tests were made on a model VSP-150 variable-speed reverse-bending plate fatigue testing machine. The endurance limit for a given grade of ductile iron is influenced by surface condition. Figure 18 shows fatigue strength curves for ferritic and pearlitic ductile iron in both the notched and unnotched conditions. The tests were made on Wohler-type fatigue machines with polished specimens 10.6 mm (0.417 in.) in diameter. Figure 19 shows that the unnotched

reversed-bending endurance limit for specimens with as-cast surfaces is considerably less than that for polished specimens of equivalent tensile strength. The absolute value of the as-cast endurance limit at any strength level depends on the surface or near-surface characteristics associated with a specific casting process. Shot blast cleaning contributes up to a 30% increase in the fatigue strength of the sand cast surface. This is controlled by the size of the shot, the size of the load, and the length of the cycle. The effect of shot blasting (shot peening) can be monitored by attaching an Almen block and strip to a sample casting and including it with the load. This should be done for any change in process.

Grade	Tensile strength		Unnotched			Notched			Stress concentration factor
			Endurance limit		Endurance ratio	Endurance limit		Endurance ratio	
	MPa	ksi	MPa	ksi		MPa	ksi		
60-40-18	480	70	205	30	0.43	125	18	0.26	1.67

Fig. 19 Effect of surface condition on endurance limit of ductile iron. Tests made on 10.6 mm (0.417 in.) diam specimens. Fully reversed stress ($R = -1$)

Ductile iron is cycle frequency sensitive. The cycle frequency used in testing should not exceed that which the part would experience in service.

The influence of tensile strength and matrix structure on the endurance ratio of ductile iron is shown in Fig. 20. Endurance ratio is defined as endurance limit divided by tensile strength. Because the endurance ratio of ductile iron declines as tensile strength increases, regardless of matrix structure, there may be little value in specifying a higher-strength ductile iron for a structure that is prone to fatigue failure; redesigning the structure to reduce stresses or strains may prove to be a better solution. For tempered martensitic ductile iron, the improvement in fatigue strength due to an increase in tensile strength is proportionately greater than for a ferritic or pearlitic grade; this is indicated by the shallower slope for martensitic ductile iron in Fig. 20.

Strain Rate Sensitivity. Ductile iron, like many steels, is strain rate sensitive. In a forming operation such as coining to a close dimension to remove a machining operation, rolling an idler arm ball socket, or thread rolling, the rate of material movement should be low enough to avoid cracking. In coining, a hydraulic press should be used when the operation is carried out at room temperature. When a stroke press is used, the part must be heated to a high enough temperature to avoid cracking during forming. When high rates of strain must be tolerated, the section size should be increased to reduce the degree of strain.

The notch sensitivity of ductile iron must be considered when designing crankshafts. The fillet in the crankpin must be a minimum of 1.65 mm (0.065 in.) thick, in contrast to 1.14 mm (0.045 in.) for the pearlitic malleable iron it replaces. It will have significantly greater fatigue strength than the part it replaces.

Ductile Iron

Revised by Lyle R. Jenkins, Ductile Iron Society; and R.D. Forrest, Pechiney Electrometallurgie, Division Fonderie

Mechanical Properties at Elevated Temperatures

The hardness and strength of all standard grades of ductile iron are relatively constant up to about 425 °C (800 °F). Hot hardness data for four annealed (ferritic) ductile irons are shown in Fig. 21. It should be noted that the hot hardness is lower with a lower silicon content.

Fig. 21 Hot hardness of four annealed (ferritic) ductile irons. Source: Ref 13

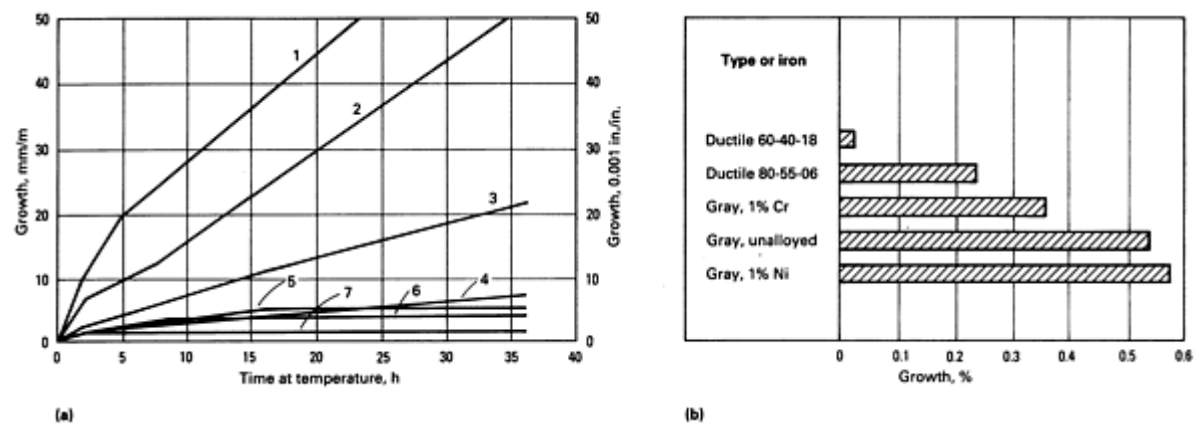

The resistance to oxidation of ductile irons and other materials at 705 °C (1300 °F) is shown in Table 10. In ductile iron, resistance to oxidation increases with increasing silicon content. The data indicate that ductile iron of normal composition has much better oxidation resistance than does cast steel, gray iron, or pearlitic malleable iron.

Table 10 Oxide penetration of ductile iron and other materials at 705 °C (1300 °F)

Material	Oxide penetration					
	2000 h		3000 h		4000 h

2.5% Si	4.8	188	3.6	143
Pearlitic malleable	3.3	131

The dimensional growth of ductile iron is much less than that of gray iron at elevated temperatures. Figure 22(a) compares the growth of ductile and gray irons at 900 °C (1650 °F). The compositions of the irons are shown in the table below the graph. Data on the growth of ductile and gray irons at 540 °C (1000 °F) for 6696 h are plotted in Fig. 22(b), which emphasizes the excellent performance of ASTM grade 60-40-18 ferritic ductile iron. Additional information on the properties of alloy ductile iron at elevated temperatures may be found in the article "Alloy Cast Irons" in this Volume.

Type of iron	Composition, %

The **creep strength** of ductile iron depends on composition and microstructure. As shown in Fig. 23(a), ferritic ductile iron has a creep resistance comparable to that of annealed low-carbon cast steel up to 650 °C (1200 °F). Table 11 shows the creep strength of ductile iron of various compositions. Representative minimum creep rates versus applied stress are shown in Fig. 23(b) and 23(c). The improvement in creep strength that can be achieved by adding molybdenum or copper is shown in Table 11 and Fig. 24. Figure 25 shows the stress necessary at a given temperature to produce a minimum creep rate of 0.0001%/h in ferritic and pearlitic ductile irons.

Ductile Iron

Revised by Lyle R. Jenkins, Ductile Iron Society; and R.D. Forrest, Pechiney Electrometallurgie, Division Fonderie

Hardenability

Ductile iron in various hardened conditions has become accepted for such applications as heavy-duty gears, spinning mandrels, pump liners, rolls, dies, clutch drums, pistons, brake drums, and agricultural-implement parts. Ductile iron has limited heat transfer characteristics because the graphite is in a spheroidal shape rather than the graphite flake form of cast iron. Spheroidal graphite (SG) iron provides an answer to the problem of heat transfer encountered with compacted graphite and yet SG iron has higher strength than gray cast iron. This is important in the case of brake drums or rotors, which may develop high braking surface temperatures and form hard spots of martensite. Alloy ductile iron can develop an acicular structure in the as-cast structure that may resemble bainite or martensite. However, the latter are structures developed by heat treatment. Most applications use quenching and tempering or isothermal transformation treatments, which provide ductile iron with a hard surface overlaying a tough core. The hardenability of ductile irons covers a wide range, but a ductile iron generally has higher hardenability than a eutectoid steel with comparable alloy content (Ref 17).

Austenitizing temperatures between 845 and 925 °C (1550 and 1700 °F) affect hardenability according to the amount of combined carbon that is taken into solution. Higher temperature and longer time, up to that required for saturation of the austenite at the soaking temperature, increase the amount of combined carbon, which increases hardenability. Graphite has lower solubility in austenite than does pearlite (combined carbon); that is, it takes a higher temperature and a longer elapse of time to harden ferritic ductile than are required for pearlitic ductile iron. The time and temperature required for pearlitic ductile iron to reach maximum hardness depend on the combined carbon content, which is to some degree related to the hardness before heat treatment. An as-cast pearlitic ductile iron will normally have a higher combined carbon content than will normalized ductile iron of the same hardness. The silicon content of ductile iron reduces the amount of carbon taken into solution.

Insufficient time or temperature used in hardening ductile iron is made obvious by a microstructure that has the appearance of bainite in the original ferrite grain boundary and of transformation products (pearlite or martensite in the center of the grains).

Ductile Iron

Revised by Lyle R. Jenkins, Ductile Iron Society; and R.D. Forrest, Pechiney Electrometallurgie, Division Fonderie

Physical Properties

Cast irons are not homogeneous materials. Certain properties are affected more by the shape, size, and distribution of the graphite particles than by any other attribute of the structure, a behavior more like that of a composite material than of a homogeneous metal or alloy. Among the physical properties of ductile iron, density is affected only by the relative amounts of the microconstituents present, not by their form or distribution, whereas thermal and electrical conductivity are markedly affected by the form and distribution of the various phases, especially graphite, which has properties very different from those of the various metallic phases. Table 12 summarizes the densities and thermal conductivities of the various microconstituents of cast iron.

Table 12 Densities and thermal conductivities of the microconstituents in cast iron

Constituent	Density ^(a)		Thermal conductivity ^(b)	
	g/cm ³	lb/in. ³	W/m · K	Btu/ft ² · h · °F
Ferrite	7.86	0.284	70-80	12.3-14.0
Austenite	7.84	0.283
Pearlite	7.78	0.281	50	8.8
Cementite	7.66	0.277	7	1.2
Martensite	7.63	0.276
Phosphide eutectic	7.32	0.264
Graphite	2.25	0.081	80-85^(c)	14-15^(c)

(a) At 20 °C (68 °F).

(b) 0 to 100 °C (32 to 212 °F).

(c) Along C-axis.

(d) Along basal plane

Density. For most ductile irons, density at room temperature is about 7.1 g/cm^3 . Density is largely affected by carbon content and by the degree of graphitization and any amount of microporosity. A low-carbon pearlitic ductile iron might have a density as high as 7.4 g/cm^3 , and a high-carbon ferritic ductile iron may have a density as low as 6.8 g/cm^3 . Microporosity, when present, will produce a lower density, depending on the amount present. High-nickel compositions, such as the Ni-Resist ductile irons, have slightly greater density, about 7.4 to 7.7 g/cm^3 .

Thermal Properties. Specific heat is relatively unaffected by composition, but of unalloyed ductile iron varies with temperature:

Temperature		Specific heat	
°C	°F	J/kg · K	Btu/lb · °F
20-200	70-390	461	0.110
20-300	70-570	494	0.118
20-400	70-750	507	0.121
20-500	70-930	515	0.123
20-600	70-1110	536	0.128
20-700	70-1290	603	0.144

The melting point varies with silicon content, and the melting range varies with carbon content. The closer the value of the carbon equivalent is to the eutectic composition, the narrower the melting range. Unalloyed and low-alloy ductile irons melt in the range of 1120 to 1160 °C (2050 to 2120 °F); austenitic high-nickel ductile irons melt at about 1230 °C (2250 °F).

The heat of fusion for all ferritic and pearlitic grades of ductile iron is about 210 to 230 kJ/kg (90 to 99 Btu/lb).

The coefficient of linear thermal expansion, like specific heat, is considered to be constant over a given temperature range even though the coefficient of thermal expansion actually varies with temperature. Because it varies with temperature, different values of expansion coefficient are needed for different temperature ranges. The value of the expansion coefficient is ordinarily determined by measuring the change in length of a

standard-size specimen as it is heated and cooled over a specific temperature range. Coefficients of linear thermal expansion for ferritic and pearlitic ductile irons are given in Table 13. Values for highly alloyed ductile irons may be considerably different from those given. The coefficient of linear thermal expansion for austempered ductile iron is related to the proportion of ferrite and retained austenite in the austempered ductile iron.

Table 13 Coefficients of thermal expansion for ferritic and pearlitic ductile irons

Temperature range		Coefficient of thermal expansion			
		Ferritic ductile iron		Pearlitic ductile iron	
°C	°F	μm/m · K	μin./in. · °F	μm/m · K	μin./in. · °F
20-110	70-230	11.2	6.23	10.6	5.89
20-200	70-390	12.2	6.78	11.7	6.51
20-300	70-570	12.8	7.12	12.4	6.89
20-400	70-750	13.2	7.34	13.0	7.23
20-500	70-930	13.5	7.51	13.3	7.39
20-600	70-1110	13.7	7.62	13.6	7.56
20-700	70-1290	13.8	7.67
20-760	70-1400	14.8	8.23	14.8	8.23

The thermal conductivity of ferritic ductile iron is about 36 W/m · K (250 Btu · in./ft² · h · °F) over the temperature range of 20 to 500 °C (70 to 930 °F). There is a slight, negative temperature dependence for thermal conductivity, causing it to drop with increasing temperature. Graphite shape and alloy content have greater influences on thermal conductivity than does temperature; for instance, increasing the nickel plus silicon content of ferritic ductile iron reduces thermal conductivity, as shown in Fig. 30. Thermal conductivities of the various microconstituents found in ductile irons are given in Table 12.

Fig. 30 Effect of nickel plus silicon on the thermal conductivity of ferritic ductile iron. Source: Ref 18

Electrical and Thermal Relationship. The electrical and thermal conductivities of cast iron, like those of many metals, are related to each other in accordance with the Wiedemann-Franz Law, which ascribes both properties to the mobility of free electrons. The shape of the graphite particles in cast iron greatly effects this relationship, as indicated in Fig. 31. The thermal conductivity of gray iron containing well-developed flake graphite is much higher than that of steel, and the electrical conductivity is much lower. As the shape of the graphite changes from flake to intermediate forms to fully spherical shapes, the difference between the thermal or electrical conductivity of the cast iron and that of steel becomes less. Accordingly, ductile irons have higher electrical conductivity and lower thermal conductivity than gray irons.

Fig. 31 Effect of graphite shape on the thermal and electrical conductivities of gray and ductile iron relative to

those of steel. Source: Ref 14

Electrical Resistivity. The reciprocal function of the electrical conductivity, or electrical resistivity, of ductile iron increases with temperature. For instance, irons with a specific resistance of 0.5 to 0.55 $\mu\Omega \cdot m$ at room temperature might have a resistance of 1.25 to 1.30 $\mu\Omega \cdot m$ at 650 °C (1200 °F). Increasing the amount of silicon in either a pearlitic or ferritic matrix also increases electrical resistivity (see Fig. 32). Increasing the amount of graphite tends to increase electrical resistivity because graphite has a high resistance, but the graphitization of pearlite or cementite to produce a ferritic matrix often results in a net decrease in resistance because of the lower electrical resistivity of ferrite. Alloying elements that dissolve in the matrix normally increase resistance, but reversals of this tendency may be observed when the relative amounts of various microconstituents are changed by the presence of the alloying element.

Fig. 32 The influence of the matrix structure and silicon content on the electrical resistivity of ductile iron at room temperature. Source: Ref 14

Magnetic properties should be determined separately for each application in which they are important. Although the properties of cast irons do not approach those of permanent magnet alloys on the one hand, or of silicon steels on the other, cast irons often are used for parts that require known magnetic properties. Cast iron can be cast into intricate shapes and sections more easily than most permanent alloys. The magnetic properties of cast irons depend largely on structure; the influence of alloying elements is indirect, derived mainly from the influence exerted on structure. A ferritic structure exhibits low hysteresis loss and high permeability, whereas a pearlitic structure exhibits high hysteresis loss and low permeability. Free cementite produces an iron with low permeability, magnetic induction, and remanence, together with high coercive force and hysteresis loss. Spheroidal graphite slightly increases hysteresis loss in pearlitic irons, but considerably reduces hysteresis loss in ferritic irons. Low-phosphorus ferritic ductile iron that is essentially free of cementite and very low in combined carbon has the highest permeability and lowest hysteresis loss of all cast irons.

In alloyed ductile irons, copper and nickel decrease permeability and increase hysteresis loss. When nickel is present in sufficient quantities to produce an austenitic matrix, ductile iron becomes paramagnetic. Manganese and chromium reduce magnetic induction, permeability, and remanent magnetism and increase hysteresis loss. Silicon has little effect on magnetic properties in pearlitic ductile iron, but slightly increases maximum permeability and reduces hysteresis loss in ferritic ductile iron.

Ductile Iron

Revised by Lyle R. Jenkins, Ductile Iron Society; and R.D. Forrest, Pechiney Electrometallurgie, Division Fonderie

Machinability

Ductile iron has been chosen in many instances on the basis of significantly lower machining costs, which resulted in lower overall cost of the part. Ductile iron has approximately the same machinability as gray iron of similar hardness. At low hardnesses (ductile iron with tensile strength up to about 550 MPa, or 80 ksi, the machinability of ductile iron is better than that of cast mild steel. At higher hardnesses, the difference in machinability between ductile iron and cast steel is less pronounced.

Recommended surface speeds for machining ductile iron castings are given in Table 14. Corresponding feeds for drilling and milling are given in Tables 15 and 16. More detailed data may be found in the article "Machining of Cast Irons" and other articles in *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. In general, the recommended cutting speeds given in Table 14 are based on a tool life of about 2 h of accumulated cutting time. Although the term recommended is used, the conditions should be considered nothing more than nominal starting conditions. In practice, recommended machining conditions may be altered as necessary to accommodate various part requirements, equipment characteristics, and manufacturing objectives.

Table 14 Speeds for machining ductile iron

Ductile iron	High-speed steel tools, m/min (sfm)								Cemented carbide tools, sfm ^(a)		
	Turning ^(b)	Drilling ^(c)	Reaming ^(d)	Tapping	Thread chasing	Milling ^(e)	Shaping ^(f) and planing	Broaching	Turning ^(b)	Reaming ^(d)	Milling ^(e)
60-45-10 with full ferritic matrix	15-46 (50-150)	24-40 (80-130)	15-30 (50-100)	6-9 (20-30)	9-21 (30-70)	15-38 (50-125)	12-30 (40-100)	6-11 (20-35)	53-120 (175-400)	23-46 (75-150)	60-120 (200-400)
Semipearlitic matrix	12-27 (40-90)	15-30 (50-100)	12-21 (40-70)	4.5-6 (15-20)	6-15 (20-50)	11-20 (35-65)	9-23 (30-75)	4.5-7.6 (15-25)	30-90 (100-300)	15-27 (50-90)	53-107 (175-350)
80-60-03 with full pearlitic matrix	12-27 (40-90)	15-21 (50-70)	12-21 (40-70)	4.5-6 (15-20)	6-15 (20-50)	11-20 (35-65)	9-23 (30-75)	4.5-7.6 (15-25)	30-90 (100-300)	15-27 (50-90)	53-107 (175-350)

(a) In all instances, the longest tool life between regrinds will result when tools are operated at minimum to median speeds for the range given.

(b) Feeds of 0.25 to 0.50 mm/rev (0.010 to 0.020 in./rev). Maximum speed is for cuts not more than 1.6 mm ($\frac{1}{16}$ in.) deep.

(c) Feeds should be commensurate with drill diameter: light feeds for small-diameter drills and heavier feeds for larger drills. For recommended feeds, see Table 15. It is good practice to reduce speed as drill diameter increases; speeds at or near the maximum values given in this table are for drills 12 mm ($\frac{1}{2}$ in.) in diameter or less.

(d) Use feeds three to four times those used for drills of similar size. An allowance of 0.30 to 0.38 mm (0.012 to 0.015 in.) is sufficient for reaming.

(e) Speeds cited are principally for face milling; however, they may be used as a guide for plain milling. For recommended feeds, see Table 16.

(f) Depth of cut and feed vary with sturdiness of the setup. The operating speed for roughing should approach the minimum value cited.

Table 15 Starting recommendations for drilling ductile irons with high-speed steel tools

Types classified by microstructure	Typical hardness, HB	Condition	Speed m/min (sfm)	Feed, mm/rev (in./rev) at nominal hole diameter, mm (in.)								High-speed steel tool material
				1.5 ($\frac{1}{16}$)	3 ($\frac{1}{8}$)	6 ($\frac{1}{4}$)	1 ($\frac{1}{2}$)	18 ($\frac{3}{4}$)	25 (1)	35 ($1\frac{1}{2}$)	50 (2)

Table 16 Feeds for milling ductile iron

Type of cutter	Feed per tooth, when using
----------------	----------------------------

	High-speed steel tools		Cemented carbide tools	
	mm	in.	mm	in.
Face mill	0.15-0.30	0.006-0.012	0.20-0.40	0.008-0.015
Plain mill	0.13-0.23	0.005-0.009	0.15-0.30	0.006-0.012
End mill	0.08-0.20	0.003-0.008	0.08-0.25	0.003-0.010
Circular saw	0.05-0.10	0.002-0.004	0.02-0.10	0.001-0.004

Note: For milling speeds, see Table 14.

Experience has shown that when converting from malleable iron or pearlitic malleable iron castings to ductile iron, surface speeds should be increased by about 20%. This allows the chip to roll faster and break easier, improving tool life and thereby providing an increase in productivity. The higher elongation of ductile iron causes the chips to roll and produce more abrasion on the tool. This added abrasion is reduced if the chip breaks instead of rolling. Also, as-cast ductile iron does not have the surface decarburized layer normally found in malleable irons that decreases tool life.

Work hardening is produced when machining ductile iron, making it important to avoid light cuts. Coolants improve high-speed tool life, but are not as effective for carbide tool life until high-surface speeds are used.

A comparison can be made between the machinability of ASTM class 40 gray iron and that of ASTM grade 60-40-18 ductile iron. The gray iron has a tensile strength of about 275 MPa (40 ksi) and a hardness of 190 to 220 HBN. The ductile irons have a yield strength of about 275 MPa (40 ksi) and a hardness of about 187 HBN. The higher silicon content of ductile iron compared to malleable iron or gray cast iron causes the ferrite to be harder. The recommended cutting speed for rough turning using a single-point high speed steel tool at a feed of about 0.38 mm/rev (0.015 in./rev) is 20 m/min (70 sfm) for ASTM class 40 gray iron and 43 m/min (140 sfm) for ASTM grade 60-40-18 ductile iron. For a similar rough turning operation, cast mild steel with a tensile strength of about 415 to 485 MPa (60 to 70 ksi) requires a cutting speed of 33 m/min (110 sfm). Replacing the high speed steel tool with one made of sintered carbides allows increases in cutting speed for all three materials, but does not change the ratios of cutting speeds among the three materials. For ductile iron, the cutting speed, using carbide tools dry, increases to about 82 m/min (270 sfm).

Example 1: Comparison of the Machinability of Ferritic Ductile Iron With That of Selected Grades of Gray Cast Iron.

For this test program, test castings representing a range of cooling conditions were produced (see Fig. 33). The five sections were then cut apart and centered, and the surfaces were turned off to depths of about 1.6 to 3.2 mm ($\frac{1}{16}$ to $\frac{1}{8}$ in.). The resulting diameters were 95, 70, 60, and 45 mm (3.75, 2.75, 2.37, and 1.75 in.). Test turning was done by making successive 0.508 mm (0.200 in.) cuts at a cutting speed of 76 m/min (250 sfm). Three cuts were made and timed for each test section. The rate of metal removal was calculated for each size, and the data are shown in Fig. 33(a).

Fig. 33 Comparison of the machinability of ductile and gray irons. (a) Metal removal rates. (b) Tool life.
Source: Ref 20

Pearlitic Ductile Irons Compared With Pearlitic Gray Irons. The test described in Example 1 compared annealed ferritic ductile iron with pearlitic gray iron of slightly higher hardness. Other data comparing pearlitic gray irons with pearlitic ductile irons show no great machinability differences when the irons are of similar hardness. The comparison of tool life in the machining of ductile and gray irons is shown in Fig. 33(b).

Ductile Irons Compared With Malleable Cast Irons. In another investigation, a comparison was made between ductile iron castings and malleable iron castings. The machining operations included facing, boring, threading, and drilling. There was no significant difference in machining costs between these two materials when the work was done on a production basis.

Welding

Special materials and techniques are available for the repair welding of ductile iron castings, or for joining ductile iron to itself or to other ferrous materials such as steel, gray iron, or malleable iron. Like the welding of other cast irons, the welding of ductile iron requires special precautions to obtain optimum properties in the weld metal and adjacent heat-affected zone. The main objective is to avoid the formation of cementite in the matrix material, which makes the welded region brittle; but in ductile iron an additional objective, that of retaining a nodular form of graphite, is of almost equal importance. The formation of martensite or fine pearlite can be removed by tempering.

A technique developed and patented by Oil City Iron Works uses a special ductile iron filler metal and a special welding flux that is introduced through a powder spray-type oxyacetylene welding torch. In this technique, which is used predominantly for the cosmetic repair of ductile iron castings, parent metal is puddled under a

neutral region of slightly reducing flame, and filler metal is added as the special flux is sprayed into the puddle through the torch. A properly executed weld will be essentially free of eutectic carbides in the weld metal and will have a pearlitic matrix with bull's-eye ferrite surrounding the particles of spheroidal graphite.

Typically, the mechanical properties of the weld metal are very similar to those of the parent metal for all heat-treated conditions: as-welded, annealed, normalized, or quenched and tempered. The only possible exception is that the ductility of the weld metal may be slightly lower than that of equivalent parent metal at the lower hardnesses, such as those typical of the as-welded or annealed conditions.

Among other advantages, this process obtains a perfect color match with the cast metal; yields weld metal with composition, microstructure, and properties very close to those of the original casting; and minimizes the transition zone, the heat-affected zone, and any residual stresses.

As an alternative to the Oil City process, ductile iron can be welded with a high-nickel alloy, using the flux-cored arc welding (FCAW) process. In flux-cored arc welding, a hollow wire with the composition 50Ni-44Fe-4.25Mn-1.0C-0.6Si and containing a special flux is used as the electrode in standard FCAW equipment. This method is used to join ductile iron to itself or to steel or other types of cast iron more often than it is used to effect the cosmetic repair of castings. The mechanical properties of the high-nickel weld metal and of the adjacent heat-affected zone are usually equivalent to the properties of ASTM grade 65-45-12 ductile iron. A major disadvantage of welding with the high-nickel alloy is that it does not respond to heat treatment, and thus weldments made with this alloy cannot be heat treated to obtain uniformly high strength levels, as can weldments made using the Oil City process.

Low-temperature welding rods and wire that have high wetting properties on cast iron base metals, are available. This effects the joining of metals at such low temperatures that the base metal does not melt. The composition of the weld metal is such that it has dimensional changes with temperature similar to those of ductile iron, thereby reducing stresses. The color match is perfect, the hardness is low, the tensile strength is greater than 390 MPa (57 ksi), and the elongation is 25 to 30%. The weld metal is suitable for tungsten inert gas welding operations. The welding rods or wire are produced by Shichiho Metal Industrial Company Ltd.

Other methods for welding ductile iron include submerged arc welding and the use of austenitic consumable materials (see Ref 21, 22, 23 and the article "Welding of Cast Irons," in *Welding*, Volume 6 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*).

Compacted Graphite Iron

Doru M. Stefanescu, The University of Alabama

Introduction

COMPACTED GRAPHITE (CG) cast iron is also referred to as vermicular graphite, upgraded, or semiductile cast iron (Ref 1). It has been inadvertently manufactured in the past in the process of producing ductile iron, as a result of undertreatment with magnesium or cerium. Since 1965, after R.D. Schelleng obtained a patent for its production, CG iron has occupied its rightful place in the family of cast irons.

The graphite morphology of CG iron is rather complex. A typical scanning electron microscope photomicrograph of a compacted graphite particle etched out of the matrix is shown in Fig. 1(a). It is seen that compacted graphite appears in clusters that are interconnected within the eutectic cells. Classical optical metallography (Fig. 1b) exhibits graphite that is similar to type IV ASTM A 247 graphite (see the article "Classification and Basic Metallurgy of Cast Iron" in this Volume). Compacted graphite appears as thicker, shorter-flake graphite. In general, an acceptable CG iron is one in which at least 80% of the graphite is compacted graphite, there is a maximum of 20% spheroidal graphite (SG), and there is no flake graphite (FG).

Fig. 1 Compacted graphite. (a) SEM photomicrograph showing deep-etched specimen. 200×. (b) Optical photomicrograph

This graphite morphology allows better use of the matrix, yielding higher strength and ductility than flake graphite cast iron. Similarities between the solidification patterns of flake and compacted graphite iron explain the good castability of the latter, compared to ductile iron (ductile iron, which is also termed nodular iron or spheroidal graphite iron, is called SG iron in this article). Also the interconnected graphite provides better thermal conductivity and damping capacity than spheroidal graphite.

Compacted Graphite Iron

Doru M. Stefanescu, The University of Alabama

Chemical Composition

The range of acceptable carbon and silicon contents for the production of CG iron is rather wide, as shown in Fig. 2. Nevertheless, the optimum carbon equivalent (CE) must be selected as a function of section thickness, in order to avoid carbon flotation when too high a CE is used, or excessive chilling tendency, when too low a CE is used. The manganese content can vary between 0.1 and 0.6%, depending on whether a ferritic or a pearlitic structure is desired. Phosphorus content should be kept below 0.06% in order to obtain maximum ductility from the matrix. The initial sulfur level should be below 0.025%, although techniques for producing CG iron from base irons with higher sulfur levels are now available (see the article "Compacted Graphite Irons" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). Residual sulfur after liquid treatment is typically in the range of 0.01 to 0.02%.

Fig. 2 Optimum range for carbon and silicon contents for CG iron. Source: Ref 2

The change in graphite morphology from the flake graphite in the base iron to the compacted graphite in the final iron is achieved by liquid treatment with different minor elements. These elements may include one or more of the following: magnesium, rare earths (cerium, lanthanum, praseodymium, and so on), calcium, titanium, and aluminum. The amounts and combinations to be used are a function of the method of liquid treatment, base sulfur, section thickness, and so forth, and are discussed in Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. For example, Fig. 3 shows some typical correlations between treatment method (level of minor elements), initial sulfur level, and graphite shape when producing CG irons.

Spheroidizer	ΔS range ^(a) for compacted iron, %
Mg + Ce	-0.0155 to -0.032
Mg + Ti > 0.10%	-0.0155 to -0.042
Mg + Ti 0.05 - 0.1% + Al 0.2 - 0.3%	-0.0110 to -0.055
Mg + Al > 0.35%	-0.0060 to -0.35

(a) ΔS : final % S - 0.34 (% residual elements) - 1.33 (% Mg)

Fig. 3 Optimum range of initial sulfur level as a function of type (figure) and amount (table) of minor elements used for graphite compaction. The above table shows the sulfur range, ΔS , for compacted iron formation with different spheroidizers in an iron composition of 3.5% C, 2.1% Si, 0.75% Mn, and 0.03 to 0.08% P. Source: Ref 1, 3

Compacted graphite iron has a strong ferritization tendency. Copper, tin, molybdenum, and even aluminum can be used to increase the pearlite/ferrite ratio. Again, the optimum amounts of these elements for a particular matrix structure are largely a function of section size.

Compacted Graphite Iron

Doru M. Stefanescu, The University of Alabama

Castability

The fluidity of cast iron is a function of its pouring temperature, composition, and eutectic morphology. A higher temperature and higher CE result in better fluidity. Everything else being equal, the fluidity of CG iron is intermediate between that of FG (highest) and SG (lowest) iron (Ref 1). However, because CG iron has a higher strength than FG iron for the same CE, high-CE compositions of CG iron can be used for the pouring of thin castings.

Shrinkage Characteristics. With CG irons, obtaining sound castings free from external and internal shrinkage porosity is easier than with SG irons and slightly more difficult than with FG irons. This is because the tendency for mold wall movement also lies between that of SG and FG irons.

In relative numbers, solidification expansion has been found to be 4.4 for SG iron and 1 to 1.8 for CG iron if FG iron is 1 (Ref 4). Because of the rather low shrinkage of CG iron, it can sometimes be cast riserless. Expensive pattern changes are therefore not necessary when converting from gray iron to CG iron because the same gating and risering techniques can be applied.

Chilling Tendency. Although many believe that the chilling tendency of CG iron is also intermediate between that of FG (lowest) and SG (highest) irons, this is not true. Figure 4 shows the influence of nodularity on the structure of chill pins cast in air set molds (Ref 5). It can be seen that the highest chilling tendency is achieved for irons with nodularities between 6 and 64%. In other words, the chilling tendency of CG iron is higher than that of both SG and FG iron. This correlates with cooling curve data (see the article "Compacted Graphite Irons" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*) and is explained by the combination of a low nucleation rate and low growth rate occurring during the solidification of CG iron.

Fig. 4 Influence of graphite shape over the chilling tendency of cast iron. Type A graphite flake: uniform distribution and random orientation. Type D graphite flake: interdendritic segregation and random orientation (see the article "Classification and Basic Metallurgy of Cast Iron" in this Volume). Source: Ref 5

Compacted Graphite Iron

Doru M. Stefanescu, The University of Alabama

Mechanical Properties at Room Temperature

The in-service behavior of many structural parts is a function not only of their mechanical strength, but also of their deformation properties. Thus it is not surprising to find that many castings fail not because of insufficient strength, but because of a low capacity for deformation. This is especially true under conditions of rapid loading and/or thermal stress. Particularly sensitive to such loading are casting zones that include some defects or abrupt changes in section thickness. The elongation values of about 1% obtainable with high-strength gray iron are insufficient for certain types of applications such as diesel cylinder heads (Ref 6). Compacted graphite irons have strength properties close to those of SG irons, at considerably higher elongations than those of FG iron, and with intermediate thermal conductivities. Consequently, they can successfully outperform other cast irons in a number of applications.

The main factors affecting the mechanical properties of CG irons both at room temperatures and at elevated temperatures are:

- Composition
- Structure (nodularity and matrix)
- Section size

In turn, the structure is heavily influenced by processing variables such as the type of raw materials, preprocessing of the melt (superheating temperature, holding time, desulfurization), and liquid treatment (graphite compaction and postinoculation).

Tensile Properties and Hardness. A comparison between some properties of FG, CG, and SG irons is given in Table 1. A listing of tensile properties of various CG irons produced by different methods is given in Table 2.

Table 1 Comparison of properties of cerium-treated CG iron with FG iron of the same chemical composition, high-strength pearlitic FG iron, and ferritic SG iron in the as-cast condition

Property	High-strength pearlitic FG iron (100% pearlite, 100% FG) ^(a)	FG iron (100% pearlite, 100% FG) ^(b)	Ce-treated CG iron (>95% ferrite, >95% CG) ^(b)	SG iron (100% ferrite, 80% SG, 20% poor SG) ^(b)

(c) Modulus of elasticity at zero stress (E_0).

Compacted graphite irons exhibit linear elasticity for both pearlitic and ferritic matrices, but to a lower limit of proportionality than does SG iron (Fig. 5). The ratio of yield strength to tensile strength ranges from 0.72 to 0.82, which is higher than that for SG iron of the same composition. This makes possible a higher loading capacity. The limit of proportionality is 125 MPa (18 ksi) for both ferritic and pearlitic CG irons. It is slightly lower than that of SG iron. This can be explained by the higher notching effect from the sharper-edged morphology of the compacted graphite compared to spheroidal graphite. Consequently, for the same stress, plastic deformation occurs sooner around the graphite in CG iron than in SG iron, causing earlier divergence from proportionality (Ref 1).

Fig. 5 Typical stress-strain curves for CG irons. The pearlitic iron had a tensile strength of 410 MPa (59.5 ksi) and an elongation of 1%. The ferritic iron had a tensile strength of 320 MPa (46.5 ksi) and an elongation of 3.5%. Source: Ref 1

As the hardness increases, tensile strength increases but elongation decreases, this being the effect of a higher pearlite/ferrite ratio (see Fig. 6). The ratio of tensile strength to Brinell hardness is somewhat higher for CG iron than for FG iron. In general, CG iron has lower hardness than an FG iron of equivalent strength because of the higher amount of ferrite in the structure. For the same elongation, CG iron has considerably less yield strength than SG iron, as shown in Fig. 7.

Fig. 6 Correlation between hardness, tensile strength, and elongation in CG irons. Source: Ref 8

Fig. 7 Correlation between yield strength and elongation for CG and SG irons. Source: Ref 8

Effect of Composition. It has been demonstrated that the tensile properties of CG irons are much less sensitive to variations in carbon equivalent than are those of FG irons. Even at CE near the eutectic value of 4.3, both pearlitic and ferritic CG irons have higher strengths than does low-CE, high-duty, unalloyed FG cast iron (Fig. 8).

Fig. 8 Effect of carbon equivalent on the tensile strength of flake, compacted, and spheroidal graphite irons cast into 30 mm (1.2 in.) diam bars. Source: Ref 10

Although increasing the silicon content decreases the pearlite to ferrite ratio in the as-cast state, both the strength and hardness of as-cast and annealed CG irons improve. This is because of the hardening of ferrite by silicon. For the same reasons, elongation in the annealed condition decreases, but increases for the as-cast state (Ref 10). Although increasing the phosphorus content slightly improves strength, a maximum of 0.04% P is desirable to avoid lower ductility and impact strength.

The pearlite/ferrite ratio, and thus the strength and hardness of CG irons, can be increased by the use of a number of alloying elements such as copper, nickel, molybdenum, tin, manganese, arsenic, vanadium, and aluminum (Ref 6, 14). The effect of copper and molybdenum on the tensile properties of CG irons is shown in Fig. 9. After annealing to a fully ferritic structure, it is possible to increase the yield point of CG iron by 24% when using 1.5% Ni (Table 3). This is because of the strengthening of the solid solution by nickel (Ref 6). The reader is cautioned, however, that additions of copper, nickel, and molybdenum may increase nodularity (Ref 6).

Table 3 Effect of heat treatment and alloying with nickel on the tensile properties of CG iron measured on a 25 mm section size

Fig. 9 Effect of (a) copper and (b) molybdenum on the tensile properties of CG iron. Source: Ref 13, 14

In order to compare the quality of different types of irons, several quality indexes can be used, such as the product of tensile strength and elongation ($TS \times El$) or the ratio of tensile strength to Brinell hardness (TS/HB). Higher values of these indexes will characterize a better iron. Using the data given in Ref 10, some typical values were calculated for these indexes for unalloyed CG irons. Figure 10 compares the $TS \times El$ product and the TS/HB ratio for unalloyed and aluminum-alloyed CG irons. It can be seen that when 2% Si is replaced by 2% Al, a much better quality CG iron is produced (Ref 11).

Fig. 10 Quality indexes for Fe-C-Si and Fe-C-Al irons. TS, tensile strength; EI, elongation. Source: Ref 11

Effect of Structure. One of the most important variables influencing the tensile properties of CG irons is nodularity. As nodularity increases, higher strength and elongation are to be expected, as shown in Table 4 and Fig. 11, although nodularity must be maintained at levels under 20% for the iron to qualify as CG iron. However, spheroidal graphite contents of up to 30% and even more must be expected in the sections of castings with considerable variation in wall thickness.

Table 4 Properties of CG iron as a function of nodularity

Nodularity, %	Tensile strength		Elongation, %	Thermal conductivity, W/(m · K)	Shrinkage, %
	MPa	ksi			
10-20	320-380	46-55	2-5	50-52	1.8-2.2
20-30	380-450	55-65	2-6	48-50	2.0-2.6
40-50	450-500	65-73	3-6	38-42	3.2-4.6

Fig. 11 Correlation between nodularity and elongation for ferritic CG iron. Source: Ref 16

As previously discussed, the pearlite/ferrite ratio can be increased by causing alloying elements. Another way of increasing or decreasing this ratio is by using heat treatment. The influence of heat treatment on mechanical properties of CG irons with 20% nodularity is given in Table 3.

Effect of Section Size. Like all other irons, CG irons are rather sensitive to the influence of cooling rate, that is, to section size, because it affects both the pearlite/ferrite ratio and graphite morphology. As mentioned before, a higher cooling rate promotes more pearlite and increased nodularity. A typical example of the influence of section size on the microstructure of CG iron is provided in Fig. 12. Although CG iron is less section sensitive than FG iron (as shown in Fig. 13 for tensile strength), the influence of cooling rate may be quite significant (see the article "Compacted Graphite Irons" in *Casting*, Volume 15 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). When the section size decreases until it is below 10 mm (0.4 in.), the tendency to increased nodularity and for higher chilling must be considered. This is particularly true for overtreated irons. While it is possible to eliminate the carbides that result from chilling by heat treatment, it is impossible to change the graphite shape, which remains spheroidal, with the associated consequences. Other factors influencing the cooling of castings, such as shakeout temperature, can also influence properties.

Fig. 13 Influence of section size on the tensile strength of CG iron. Source: Ref 15

Compressive Properties. The stress-strain diagram for compression and tensile tests of CG iron is shown in Fig. 14. It can be seen that an elastic behavior occurs up to a compression stress of 200 MPa (30 ksi). Some compressive properties of the 179 HB as-cast ferritic CG iron in Table 2 are compared with those of SG iron in Table 5. It can be seen that the 0.1% proof stress in compression for CG iron is 76 MPa (11 ksi) higher than the 0.1% proof stress in tension, while for SG iron the difference is only 23 MPa (3.3 ksi). Compressive strengths up to 1400 MPa (203 ksi) have been reported for ferritic annealed CG irons (Ref. 8).

Table 5 Comparison of tensile and compressive properties of CG and SG irons

Property	CG iron	SG iron	
Tensile strength, MPa (ksi)	380 (55)	370 (54)	420 (61)
0.1% proof stress, MPa (ksi)	246 (35.7)	224 (32.5)	261 (37.8)
0.2% proof stress, MPa (ksi)	242 (35.1)	236 (34.2)	273 (39.6)
Compressive stress			
0.1% proof stress, MPa (ksi)	322 (46.7)	247 (35.8)	284 (41.2)
0.2% proof stress, MPa (ksi)	350 (50)	250 (36.3)	287 (41.6)

Source: Ref 6

Fig. 14 Stress-strain curves in compression and tension for CG iron with 4.35 carbon equivalent. Source: Ref 9

Shear Properties. For a pearlitic CG iron, the shear strength on 20 mm (0.8 in.) diam specimens was measured at 365 MPa (53 ksi), with a shear-to-tensile strength ratio of 0.97 (Ref 17). Ratios of 0.90 for SG iron and of 1.1 to 1.2 for FG iron have been reported. Materials exhibiting some ductility have ratios lower than 1.0 (Ref 8).

Modulus of Elasticity. As is evident from Fig. 5 and 14, CG irons exhibit a clear zone of proportionality, both in tension and in compression. Typical values for both static and dynamic (resonance frequency method) measurements are given in Table 2. Dynamic tests give slightly higher numbers. In general, the moduli of elasticity for CG iron are similar to those of high-strength FG irons and can even be higher as nodularity increases.

The elasticity modulus measured by the tangent method depends on the level of stress, as shown in Fig. 15. A comparison of the stress dependency of the elasticity modulus for different types of cast irons is shown in Fig. 16. Poisson's ratios of 0.27 to 0.28 have been reported for CG irons (Ref 8).

Fig. 15 Stress dependency by E-modulus for two heat-treated CG irons. Source: Ref 6

Fig. 16 Influence of stress level on the elasticity modulus (a) in tension and (b) in compression for pearlitic FG, CG, and SG irons. Source: Ref 6

Impact Properties. While SG iron exhibits substantially greater toughness at low pearlite contents, pearlitic CG irons have impact strengths equivalent to those of SG irons (Fig. 17). Charpy impact energy measurements at 21 °C (70 °F) and -41 °C (-42 °F) showed that CG irons produced from an SG-base iron absorbed greater energy than those made from gray iron-base iron (Ref 10). This is attributed to the solute hardening effects of tramp elements in the gray iron.

Fig. 17 Effect of pearlite content on the 21 °C (70 °F) Charpy V-notch impact strength of as-cast CG irons compared to that of SG iron. Source: Ref 10

The results from dynamic tear tests were similar, although greater temperature dependence was observed. A comparison of the dynamic tear energies of CG cast irons is presented in Fig. 18. It is noted that significant differences in the values obtained occur in the ferritic condition, but that equivalent values are obtained when the matrix structure is primarily pearlitic.

Fig. 18 Dynamic tear energy versus temperature for (a) CG and (b) SG irons. Source: Ref 10

Studies on crack initiation and growth under impact loading conditions showed that, in general, the initiation of matrix cracking was preceded by graphite fracture at the graphite-matrix interface, or through the graphite, or both. The most dominant form of graphite fracture appeared to be that occurring along the boundaries between graphite crystallites (Ref 18). Matrix cracks were usually initiated in the ferrite by transgranular cleavage (graphite was nearly always surrounded by ferrite), although in some instances intergranular ferrite fracture appeared to be the initiating mechanism. Matrix crack propagation generally occurred by a brittle cleavage mechanism, transgranular in ferrite, and interlamellar in pearlite. In general, the impact resistance of CG irons increases with carbon equivalent and decreases with phosphorous or increasing pearlite.

As may be seen in Table 6, cerium-treated CG irons seem to exhibit a higher impact energy than magnesium-titanium-treated irons. It is thought that this may be attributed to TiC and TiCN inclusions present in the matrix of magnesium-titanium-treated CG irons (Ref 6).

Table 6 Impact toughness of a cerium-treated CG cast iron and two magnesium-titanium-treated CG cast irons

Iron	Structural condition and graphite type	Test temperature		Impact bend toughness ^(a)		Notched-bar ^(b) impact toughness	
		°C	°F	J	ft · lbf	J	ft · lbf
Cerium-treated (150 HB iron in Table 2)	>95% ferrite (as-cast); 95% CG, 5% SG	20	68	32.1	23.7	6.5	4.8
		-20	-4	26.5	19.5	4.6	3.4
		-40	-40	26.7	19.7	5.0	3.7
Magnesium (0.018%) and titanium (0.089%) treated	100% ferrite (annealed); CG	20	68	13.5-19	10-14	5.4	4.0

(a) Unnotched 10 × 10 mm (Charpy) testpiece.

(b) V-notched 10 × 10 mm (Charpy) testpiece.

Fatigue Strength. Because the notching effect of graphite in CG iron is considerably lower than that in FG irons, it is expected that CG iron will have higher fatigue strengths than FG iron (Table 1). Table 7 lists the fatigue strengths of five CG irons from Table 2. The as-cast ferritic (>95% ferrite) CG with a hardness of 150 HB had the highest fatigue strength and the highest fatigue-endurance ratio (fatigue strength/tensile strength). Fatigue properties for three of these CG irons with comparable endurance ratios are shown in Fig. 19. It is evident that pearlitic structures, higher nodularity, and unnotched samples resulted in better fatigue strength. The fatigue-endurance ratio was 0.46 for a ferritic matrix, 0.45 for a pearlitic matrix, and 0.44 for a pearlitic higher-nodularity CG iron (Ref 17). With fatigue notch factors (ratio of unnotched to notched fatigue strength) of 1.71 to 1.79, CG iron is almost as notch sensitive as SG iron (>1.85). Gray iron is considerably less notch sensitive, with a notch factor of less than 1.5 (Ref 6).

Table 7 Fatigue strengths and endurance ratios for five CG irons from rotating bending tests

Matrix structure	Graphite type	Tensile strength	Fatigue strength	Fatigue-endurance ratio	Hardness, HB
------------------	---------------	------------------	------------------	-------------------------	--------------

		MPa	ksi	MPa	ksi	ratio	
As-cast ferrite (>95% ferrite)	95% CG	336	48.7	211	30.6	0.63	150
As-cast ferrite	CG	388	56.3	178	25.8	0.46	184
As-cast pearlite	CG	414	60	185	26.8	0.45	205
As-cast pearlite	CG + SG	473	68.6	208	30.2	0.44	217

Source: Ref 6

Fig. 19 Fatigue curves in rotating bending tests for ferritic, pearlitic, and higher nodularity CG irons from Table 7. Source: Ref 17

Statistical analysis of a number of experimental data allowed the calculation of a relationship between fatigue strength (FS) and tensile strength (TS) of CG irons (Ref 6):

$$FS \text{ (in MPa)} = (0.63 - 0.00041 \cdot TS) \cdot TS \text{ (in MPa)} \quad (\text{Eq 1})$$

Values calculated with this equation fit well between those of FG and SG irons. The intermediate position of CG irons from this standpoint is also shown in Fig. 20.

Fig. 20 Ratio of alternating bend fatigue strength/tensile strength of FG, CG, and SG irons. Source: Ref 6

A 36% decrease of the alternating bending fatigue strength was observed on unnotched bars with casting skin compared to machined bars. This compares with a 50% reduction for comparable strength FG iron and a 32% reduction for ferritic SG iron.

Compacted Graphite Iron

Doru M. Stefanescu, The University of Alabama

Elevated-Temperature Properties

Tensile Properties. The variation of tensile properties with temperature for CG iron produced with cerium-mischmetal treatment alloys is similar to that typical for SG iron (Fig. 21), but the values are somewhat lower (Ref 19). Similar results are reported for CG irons produced with Mg-Ti-ferrosilicon alloys shown in Fig. 22. As expected, a slight increase in nodularity led to higher tensile strength values at all temperatures.

Fig. 21 Variation of tensile properties of Ce-treated CG and SG irons with temperature. Source: Ref 19

Fig. 22 Variation of tensile properties of Mg+Ti-treated CG irons. Source: Ref 20

Growth and Scaling. Tests conducted for 32 weeks in air have shown that at 500 °C (930 °F) the growth and scaling of CG iron was not significantly different from that exhibited by FG irons of similar composition. However, at 600 °C (1110 °F), the growth of CG irons was less than that of FG iron, and scaling resistance was superior (Fig. 23).

Fig. 23 Scaling and growth of heavy section flake and compacted graphite cast irons at 600 °C (1110 °F). Source: Ref 9

In other oxidation studies of cast irons conducted at 600 °C (1110 °F), it was concluded that weight gains due to oxidation are 10 to 15% higher for CG irons than for SG irons, but 30 to 60% lower for CG irons than for FG irons (Ref 21).

Thermal Fatigue. When castings are used in an environment where frequent changes in temperature occur, or where temperature differences are imposed on a part, thermal stresses occur in castings and may result in elastic and plastic strains and finally in crack formation. The casting can thus be destroyed as a result of thermal fatigue. Changes in microstructure, associated with stress-including volume changes, as well as surface and internal oxidation, may also be associated with temperature difference induced stresses.

The interpretation of thermal fatigue tests is complicated by the many different test methods employed by various investigators. The two widely accepted methods are constrained thermal fatigue and finned-disk thermal shock tests (Ref 22, 23).

In the constrained thermal fatigue test, a specimen (see Fig. 24 (a) for dimensions) is mounted between two stationary plates that are held rigid by two columns, heated by high frequency (450 kHz) induction current, and cooled by conduction of heat to water-cooled grips (Fig. 24(b)). The thermal stress that develops in the test specimen is monitored by a load cell installed in one of the grips holding the specimen. During thermal cycling, compressive stresses develop upon heating, and tensile stresses develop upon cooling. As thermal cycling continues, the specimen accumulates fatigue damage in a fashion similar to that in mechanical fatigue testing; ultimately, the specimen fails by fatigue. Initially the specimen develops compressive stress upon heating due to constrained thermal expansion (Fig. 25). Some yielding and stress relaxation occur during holding at 540 °C (1000 °F), and upon subsequent cooling the specimen develops residual tensile stress. During subsequent

thermal cycling, the maximum compressive stress that has developed upon heating decreases continuously, and the maximum tensile stress upon cooling increases, as shown for six different irons in Fig. 26.

Fig. 24 (a) Dimensions of constrained fatigue test specimen. (b) Schematic of apparatus for constrained fatigue tests. Dimensions given in millimeters. Source: Ref 23

Fig. 25 Typical thermal stress cycles at the beginning of the test for FG and CG irons. Source: Ref 23

Fig. 26 The shift in thermal stress versus the number of cycles for six irons cycled between 100 and 540 °C (212 and 1000 °F). Source: Ref 23

Experimental results (Fig. 27) point to higher thermal fatigue for CG iron than for FG iron and also indicate the beneficial effect of molybdenum. In fact, regression analysis of experimental results indicates that the main factors influencing thermal fatigue are tensile strength (TS) and molybdenum content:

$$\log N = 0.934 + 0.026 \cdot TS + 0.861 \cdot Mo \quad (\text{Eq 2})$$

where N is the number of thermal cycles to failure, tensile strength is in kps per square inch (ksi), and molybdenum is in percent.

Fig. 27 Results of constrained thermal fatigue tests conducted between 100 and 540 °C (212 and 1000 °F). Source: Ref 23

In the finned-disk thermal shock test, the specimen (see Fig. 28a for dimensions) is cycled between a moderate-temperature environment and a high-temperature environment, which causes thermal expansion and contraction. The thermal shock test apparatus is shown in Fig. 28(b). Because in this type of test thermal conductivity plays a significant role, FG iron showed much greater resistance to cracking than did CG iron. Major cracking occurred in less than 200 cycles in all CG iron specimens, while the unalloyed FG iron developed minor cracking after 500 cycles and major cracking after 775 cycles. The alloyed FG iron, because of its higher elevated-temperature strength, did not show any sign of cracking even after 2000 cycles (Ref 23). The CG iron containing more ferrite had a slightly better thermal fatigue resistance than the CG iron with less ferrite.

Fig. 28 (a) Dimensions (in millimeters) of finned-disk specimen. (b) Schematic of apparatus for finned-disk thermal shock test. Source: Ref 23

In general, for good resistance to thermal fatigue, cast irons must have high thermal conductivity; low modulus of elasticity; high strength at room and elevated temperatures; and, for use above 500 to 550 °C (930 to 1020 °F), resistance to oxidation and structural change. The relative ranking of irons varies with test conditions. When high cooling rates are encountered, experimental data and commercial experience show that thermal conductivity and a low modulus of elasticity are most important. Consequently, gray irons of high carbon content (3.6 to 4%) are superior (Ref 22, 23). When intermediate cooling rates exist, ferritic SG and CG irons have the highest resistance to cracking, but are subject to distortion. When low cooling rates exist, high-strength pearlitic SG irons or SG irons alloyed with silicon and molybdenum are best with regard to cracking and distortion (Fig. 29).

A rather detailed analysis of the behavior of various irons at elevated temperatures is given in Ref 6. Extensive experimental work on cylinder heads is reviewed. A critical analysis of most of the accepted criteria for assessing the quality of irons for castings used at elevated temperatures is also included.

Compacted Graphite Iron

Doru M. Stefanescu, The University of Alabama

Physical Properties

Thermal conductivity plays a significant role in structural components subjected to thermal stress. The higher the thermal conductivity, the lower the thermal gradients throughout the casting, and therefore the lower the thermal stresses. The microstructure of cast iron, and especially graphite morphology, greatly influence thermal conductivity, as implied by the data shown in Table 8. Graphite exhibits the highest thermal conductivity of all the metallographic constituents. The conductivity of graphite parallel to the basal plane is about four times higher than that perpendicular to its basal plane (Ref 24). Consequently, FG has higher thermal conductivity than SG (Fig. 30). It is therefore expected that FG iron will have higher thermal conductivity than SG iron, which in turn will be better than that of steel, as shown in Fig. 31 (Ref 26). Not unexpectedly, as the amount of graphite increases, thermal conductivity is also improved.

Table 8 Thermal conductivity of structural constituents in iron-base alloys

Structural constituents	Thermal conductivity, W/(cm · K)		
	0-100 °C (32-212 °F)	500 °C (930 °F)	1000 °C (1830 °F)

Source: Ref 1

Fig. 30 Mechanism of heat conduction in various Fe-C alloys. Source: Ref 25

Fig. 31 Influence of graphite shape on the relative thermal and electrical conductivities of Fe-C alloys. Source: Ref 26

The thermal conductivity of ferrite is reduced by dissolved alloying elements. For steel, the conductivity of the matrix can be calculated by the equation (Ref 6):

$$\lambda = \lambda_0 - \ln \Sigma C \quad (\text{Eq 3})$$

where λ is the thermal conductivity of alloyed steel, λ_0 is the thermal conductivity of unalloyed steel, and ΣC is the sum of alloying elements in %. This equation can also be used to estimate the influence of various alloying additions on the conductivity of cast irons.

Typical values for the thermal conductivity of CG iron at room temperature are given in Table 2, and various cast irons are compared in Table 9. From this last table it can be seen that the thermal conductivity of CG iron is very close to that of gray cast iron and considerably higher than that of SG iron (Ref 1, 9). This behavior is explained by the fact that much like flake graphite, compacted graphite is interconnected. As for FG irons, increasing the carbon equivalent results in higher thermal conductivity for CG iron. As the temperature is increased, the thermal conductivity reaches a maximum at about 200 °C (390 °F), an effect also shown by SG irons, but not by FG iron (Fig. 32). The thermal conductivity of a typical CG iron mold is compared in Fig. 33 with results for an ingot mold and bottom plate made from FG iron and a sample of ferritic SG iron (Ref 27). As previously implied, increased nodularity results in lower thermal conductivity (Ref 1, 28).

Table 9 Thermal conductivities of FG, CG, and SG irons at various temperatures

Graphite shape	Carbon equivalent	Thermal conductivity, W/m · K (Btu/ft · h · °F)				
		100 °C (212 °F)	200 °C (390 °F)	300 °C (570 °F)	400 °C (750 °F)	500 °C (930 °F)
Flake	3.8	50.24 (29.02)	48.99 (28.30)	45.22 (26.12)	41.87 (24.19)	38.52 (22.25)
	4.8	53.39 (30.84)	50.66 (29.27)	47.31 (27.33)	43.12 (24.91)	38.94 (22.49)
Compacted	3.9	38.10 (22.01)	41.0 (23.69)	39.40 (22.76)	37.30 (21.55)	35.20 (20.34)
	4.1	43.54 (25.15)	43.12 (24.91)	40.19 (23.22)	37.68 (21.77)	35.17 (20.32)
Spheroidal	4.2	32.34 (18.68)	34.75 (20.08)	33.08 (19.11)	31.40 (18.14)	29.31 (16.93)

Fig. 32 Thermal conductivities of various cast irons. Source: Ref 1

Fig. 33 Thermal conductivities of different materials for ingot molds. Source: Ref 27

Thermal Expansion. For irons of similar chemical composition, there seems to be no difference in total-expansion regardless of graphite shape (Ref 28). However, when different compositions are used in order for an iron to fall in a typical range for a given type of cast iron, the linear expansion of CG iron is between that of SG and FG irons (Fig. 34) (Ref 1).

Fig. 34 Linear thermal expansion of various cast irons. Source: Ref 1

Sonic and Ultrasonic Properties. Resonant frequency (sonic testing) and ultrasonic velocity measurements provide reliable methods for verifying the structure and properties of castings. As shown in Fig. 35, ultrasonic velocity is directly related to nodularity. Unfortunately it is rather difficult to distinguish between CG and low-nodularity SG irons. Better results seem to be obtained when ultrasonic velocity is related to tensile strength. Figure 36 shows the correlation between tensile strength and ultrasonic velocity or resonant frequency for test bars of 30 mm (1.2 in.) diameter.

Fig. 35 Correlation between ultrasonic velocity and nodularity. Source: Ref 13

(a)

(b)

Fig. 36 Tensile strength related to (a) ultrasonic velocity and (b) resonant frequency for cast irons of varying graphite structures. Source: Ref 9

When these tests are applied to castings, the ultrasonic velocity for CG structures is independent of the shape of the casting, but should be calibrated for the section thickness. Thus, for 30 mm (1.2 in.) diam bars, the range associated with CG is between 5.2 and 5.45 km/s, but for very large castings such as ingot molds, the ultrasonic velocity for good CG structures lies between 4.85 and 5.10 km/s. Sonic testing, on the other hand, must be calibrated for a particular design of casting, for which examples of satisfactory and unsatisfactory structures must be previously checked to provide a calibration range (Ref 9).

Compacted Graphite Iron

Doru M. Stefanescu, The University of Alabama

Other Properties

Corrosion Resistance. At room temperature, the corrosion rate of CG iron in 5% sulfuric acid is nearly half that of FG iron but higher than that of SG iron (Fig. 37). With increasing temperature, the difference becomes smaller. The pearlitic matrix has higher corrosion resistance than the ferritic one. As expected, corrosion accelerates when stress is applied (Ref 29). Detailed information on the corrosion resistance of cast irons is available in the article "Corrosion of Cast Irons" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Machinability. Standardized machinability tests comparing CG irons with other castings are difficult to find in the literature. The results of drill tests on castings shown in Fig. 38 seem to indicate that the machinability is similar to that of ductile iron and that the wear of the drill is greater than for FG iron.

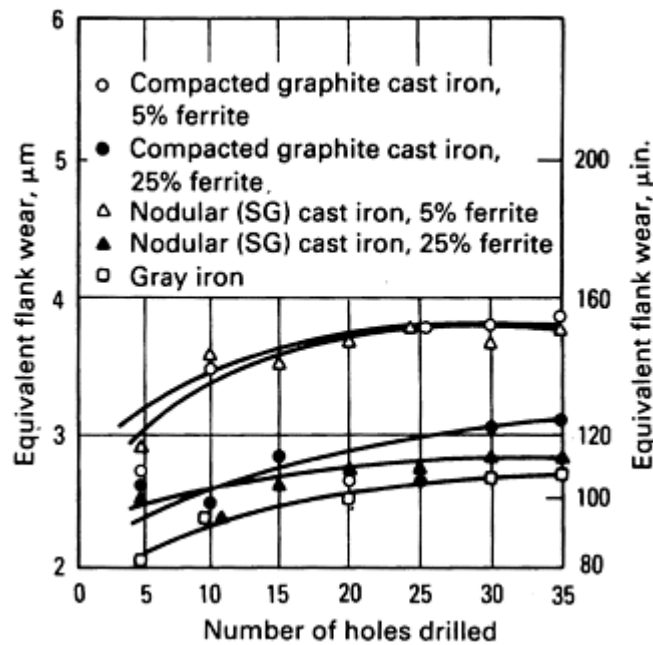

Fig. 38 Drill wear on various cast irons(drill speed, 780 rpm; rate of feed, 72 mm/min). Source: Ref 9

Nevertheless, in general, from both experimental data and practical experience in machine shops, it can be concluded that for a given matrix the machinability of CG iron is between that of gray and ductile iron (Ref 1, 9, 21). The CG morphology makes the iron sufficiently brittle for machine swarf to break into small chips, yet strong enough to prevent the swarf from forming powdery chips. Neither large swarf nor fine, powdery swarf is ideal for high machinability (Ref 10).

Damping Capacity. The relative damping capacity of various irons, obtained by measuring the relative rates at which the amplitude of an imposed vibration decreases with time, Ref 17, is:

$$\text{FG iron:CG iron:SG iron} = 1.0:0.6:0.34 \quad (\text{Eq 4})$$

Apparently, changes in the carbon equivalent or matrix do not significantly influence the damping capacity, but heavier sections will produce higher damping capacities (Ref 9).

Applications

The applications of CG irons stem from their relative intermediate position between FG and SG irons. Compared to FG irons, CG irons have certain advantages:

- Higher tensile strength at the same carbon equivalent, which reduces the need for expensive alloying elements such as nickel, chromium, copper, and molybdenum
- Higher tensile strength to hardness ratio
- Much higher ductility and toughness, which result in a higher safety margin against fracture
- Lower oxidation and growth at high temperatures
- Less section sensitivity for heavy sections

Compared to SG irons, certain advantages can be claimed for CG irons:

- Lower coefficient of thermal expansion
- Higher thermal conductivity
- Better resistance to thermal shock
- Higher damping capacity
- Better castability, leading to higher casting yield, and the capability for pouring more intricate castings
- Improved machinability

CG iron can be substituted for FG iron in all cases in which the strength of FG iron has become insufficient, but in which a change to SG iron is undesirable because of the less favorable casting properties of the latter. Examples include bed plates for large diesel engines, crankcases, gearbox housings, turbocharger housings, connecting forks, bearing brackets, pulleys for truck servodrives, sprocket wheels, and eccentric gears.

Because the thermal conductivity of CG iron is higher than that of SG iron, CG iron is preferred for castings operating at elevated temperature and/or under thermal fatigue conditions. Applications include ingot molds, crankcases, cylinder heads, exhaust manifolds, and brake disks.

The largest industrial application by weight of CG iron produced is for ingot molds weighing up to 54 Mg (60 tons). According to a number of reports summarized in Ref 30, the life of ingot molds made of CG iron is 20 to 70% longer than the life of those made of FG iron.

In the case of cylinder heads, it was possible to increase engine output by 50% by changing from alloyed FG iron to ferritic CG iron (Ref 1). The specified minimum values for cylinder heads are 300 MPa (43 ksi) tensile strength, 240 MPa (35 ksi) yield strength, and 2% elongation.

Modern car and truck engines require that manifolds work at temperature ranges of 500 °C (930 °F). At this temperature, FG iron manifolds are prone to cracking, while SG iron manifolds tend to warp. CG iron manifolds warp and oxidize less and thus have a longer life. Other engineering applications are summarized in Ref 1 and 30.

Introduction

MALLEABLE IRON is a type of cast iron that has most of its carbon in the form of irregularly shaped graphite nodules instead of flakes, as in gray iron, or small graphite spherulites, as in ductile iron. Malleable iron is produced by first casting the iron as a white iron and then heat treating the white cast iron to convert the iron carbide into the irregularly shaped nodules of graphite. This form of graphite in malleable iron is called temper carbon because it is formed in the solid state during heat treatment.

Malleable iron, like ductile iron, possesses considerable ductility and toughness because of its combination of nodular graphite and a low-carbon metallic matrix. Consequently, malleable iron and ductile iron are suitable for some of the same applications requiring good ductility and toughness, with the choice between malleable and ductile iron based on economy and availability rather than properties. However, because solidification of white iron throughout a section is essential in the production of malleable iron, ductile iron has a clear advantage when the section is too thick to permit solidification as white iron. Malleable iron castings are produced in section thicknesses ranging from about 1.5 to 100 mm ($\frac{1}{16}$ to 4 in.) and in weights from less than 0.03 to 180 kg ($\frac{1}{16}$ to 400 lb) or more.

Ductile iron also has clear advantages over malleable iron when low solidification shrinkage is needed. In other applications, however, malleable iron has a distinct advantage over ductile iron. Malleable iron is preferred in the following applications:

- Thin-section casting
- Parts that are to be pierced, coined, or cold formed
- Parts requiring maximum machinability
- Parts that must retain good impact resistance at low temperatures
- Parts requiring wear resistance (martensitic malleable iron only)

Malleable iron (and ductile iron as well) also exhibits high resistance to corrosion, excellent machinability, good magnetic permeability, and low magnetic retention for magnetic clutches and brakes. The good fatigue strength and damping capacity of malleable iron are also useful for long service in highly stressed parts.

Metallurgical Factors

Although variations in heat treatment can produce malleable irons with different matrix microstructures (that is, ferritic, tempered pearlitic, tempered martensitic, or bainitic microstructures), the common feature of all malleable irons is the presence of uniformly dispersed and irregularly shaped graphite nodules in a given matrix microstructure. These graphite nodules, known as temper carbon, are formed by annealing white cast iron at temperatures that allow the decomposition of cementite (iron carbide) and the subsequent precipitation of temper carbon.

The desired formation of temper carbon in malleable irons has two basic requirements. First, graphite should not form during the solidification of the white cast iron, and second, graphite must also be readily formed during the annealing heat treatment. These two metallurgical requirements influence the useful compositions of

malleable irons and the melting, solidification, and annealing procedures (see the article "Classification and Basic Metallurgy of Cast Iron" in this Volume for an introduction to the metallurgy of malleable iron). Metallurgical control is based on the following criteria:

- Produce solidified white iron throughout the section thickness
- Anneal on an established time-temperature cycle set to minimum values in the interest of economy
- Produce the desired graphite distribution (nodule count) upon annealing

Changes in melting practice or composition that would satisfy the first requirement listed above are generally opposed to satisfaction of the second and third, while attempts to improve annealability beyond a certain point may result in an unacceptable tendency for the as-cast iron to be mottled instead of white.

Composition. Because of the two metallurgical requirements described above, malleable irons involve a limited range of chemical composition and the restricted use of alloys. The chemical composition of malleable iron generally conforms to the ranges given in Table 1. Small amounts of chromium (0.01 to 0.03%), boron (0.0020%), copper ($\sim 1.0\%$), nickel (0.5 to 0.8%), and molybdenum (0.35 to 0.5%) are also sometimes present.

Table 1 Typical compositions for malleable iron

Element	Composition, %	
	Ferritic	Pearlitic
Total carbon	2.2-2.9	2.0-2.9
Silicon	0.9-1.9	0.9-1.9
Manganese	0.2-0.6	0.2-1.3
Sulfur	0.02-0.2	0.05-0.2
Phosphorus	0.02-0.2	0.02-0.2

The common elements in malleable iron are generally controlled within about ± 0.05 to $\pm 0.15\%$. A limiting minimum carbon content is required in the interest of mechanical quality and annealability because decreasing carbon content reduces the fluidity of the molten iron, increases shrinkage during solidification, and reduces annealability. A limiting maximum carbon content is imposed by the requirement that the casting be white as-cast. The range in silicon content is limited to ensure proper annealing during a short-cycle high-production annealing process and to avoid the formation of primary graphite (known as mottle) during solidification of the white iron. Manganese and sulfur contents are balanced to ensure that all sulfur is combined with manganese and that only a safe, minimum quantity of excess manganese is present in the iron. An excess of either sulfur or manganese will retard annealing in the second stage and therefore increase annealing costs. The chromium content is kept low because of the carbide-stabilizing effect of this element and because it retards both the first-stage and second-stage annealing reactions.

A mixture of gray iron and white iron in variable proportions that produces a mottled (speckled) appearance is particularly damaging to the mechanical properties of the annealed casting, whether ferritic or pearlitic malleable iron. Primary control of mottle is achieved by maintaining a balance of carbon and silicon contents.

Because economy and castability are enhanced when the carbon and silicon contents of the base iron are in the higher proportions of their respective ranges, some malleable iron foundries produce iron with carbon and silicon contents at levels that might produce mottle and then add a balanced, mild carbide stabilizer to prevent mottle during casting. Bismuth and boron in balanced amounts accomplish this control. A typical addition is 0.01% Bi (as metal) and 0.001% B (as ferroboration). Bismuth retards graphitization during solidification; small amounts of boron have little effect on graphitizing tendency during solidification, but accelerate carbide decomposition during annealing. The balanced addition of bismuth and boron permits the production of heavier sections for a given base iron or the utilization of a higher-carbon higher-silicon base iron for a given section thickness.

Tellurium can be added in amounts from 0.0005 to 0.001% to suppress mottle. Tellurium is a much stronger carbide stabilizer than bismuth during solidification, but also strongly retards annealing if the residual exceeds 0.003%. Less than 0.003% residual tellurium has little effect on annealing, but has a significant influence on mottle control. Tellurium is more effective if added together with copper or bismuth.

Residual boron should not exceed 0.0035% in order to avoid module alignment and carbide formation. Also, the addition of 0.005% Al to the pouring ladle significantly improves annealability without promoting mottle.

Melting Practices. (Ref 2). The iron for most present-day malleable iron is melted in coreless induction furnaces rather than the previous air furnace, cupola-air furnace, or cupola-electric furnace systems. The sulfur and nitrogen contents of the charge carbon used in melting must be high enough to provide 0.07 to 0.09% S and 80 to 120 ppm N in the iron. The sulfur reduces the surface tension and improves fluidity. The nitrogen increases the tensile strength without impairing elongation and toughness. Long holding periods in the molten state in the furnace and excessive superheating temperatures should be avoided, because they give rise to an unsatisfactory solidification structure, which in turn results in unsatisfactory heat-treated structures (Ref 2).

Melting can be accomplished by batch cold melting or by duplexing. Cold melting is done in coreless or channel-type induction furnaces, electric arc furnaces, or cupola furnaces. In duplexing, the iron is melted in a cupola or electric arc furnace, and the molten metal is transferred to a coreless or channel-type induction furnace for holding and pouring. Charge materials (foundry returns, steel scrap, ferroalloys, and, except in cupola melting, carbon) are carefully selected, and the melting operation is well controlled to produce metal having the desired composition and properties. Minor corrections in composition and pouring temperature are made in the second stage of duplex melting, but most of the process control is done in the primary melting furnace (Ref 2).

Molds are produced in green sand, silicate CO₂ bonded sand, or resin-bonded sand (shell molds) on equipment ranging from highly mechanized or automated machines to that required for floor or hand molding methods, depending on the size and number of castings to be produced. In general, the technology of molding and pouring malleable iron is similar to that used to produce gray iron.

Solidification. Molten iron produced under properly controlled melting conditions solidifies with all carbon in the combined form, producing the white iron structure fundamental to the manufacture of either ferritic or pearlitic malleable iron (Fig. 1). The base iron must contain balanced quantities of carbon and silicon to simultaneously provide castability, white iron in even the thickest sections of the castings, and annealability; therefore, precise metallurgical control is necessary for quality production. Thick metal sections cool slowly during solidification and tend to graphitize, producing mottled or gray iron. This is undesirable, because the graphite formed in mottled iron or rapidly cooled gray iron is generally of the type D configuration, a flake form in a dense, lacy structure, which is particularly damaging to the strength, ductility, and stiffness characteristics of both ferritic and pearlitic malleable iron.

Fig. 1 Structure of as-cast malleable white iron showing a mixture of pearlite and eutectic carbides. 400×

After it solidifies and cools, the metal is in a white iron state, and gates, sprues, and feeders can be removed easily from the castings by impact. This operation, called spruing, is generally performed manually with a hammer because the diversity of castings produced in the foundry makes the mechanization or automation of spruing very difficult. After spruing, the castings proceed to heat treatment, while gates and risers are returned to the melting department for reprocessing.

First-Stage Anneal. Malleable iron castings are produced from the white iron by an annealing process that converts primary carbides into temper carbon. This initial anneal is then followed by additional heat treatments that produce the desired matrix microstructures. This section focuses on the initial (first-stage) anneal that produces the temper carbon in blackheart malleable iron. The additional heat treatments used to produce the desired matrix microstructure are discussed in the sections relating to ferritic, pearlitic, or martensitic microstructures.

During the first-stage annealing cycle, the carbon that exists in combined form, either as massive carbides or as a microconstituent in pearlite, is converted into nodules of graphite (temper carbon). The rate of annealing of a hard iron casting depends on chemical composition, nucleation tendency (discussed in the section "Control of Nodule Count" in this article), and annealing temperature. With the proper balance of boron content and graphitic materials in the charge, the optimum number and distribution of graphite nuclei are developed in the early portions of first-stage annealing, and growth of the temper carbon particles proceeds rapidly at any annealing temperature. An optimum iron will anneal completely through the first-stage reaction in approximately $3\frac{1}{2}$ h at 940 °C (1720 °F). Irons with lower silicon contents or less-than-optimum nodule counts may require as much as 20 h for completion of first-stage annealing.

The temperature of first-stage annealing exercises considerable influence on the rate of annealing and the number of graphite particles produced. Increasing the annealing temperature accelerates the rate of decomposition of primary carbide and produces more graphite particles per unit volume. However, high first-stage annealing temperatures can result in excessive distortion of castings during annealing, which leads to straightening of the casting after heat treatment. Annealing temperatures are adjusted to provide maximum practical annealing rates and minimum distortion and are therefore controlled within the range of 900 to 970 °C (1650 to 1780 °F). Lower temperatures result in excessively long annealing times, while higher temperatures produce excessive distortion.

Annealing is done in high-production controlled-atmosphere continuous furnaces or batch-type furnaces, depending on production requirements. The furnace atmosphere for producing malleable iron in continuous furnaces is controlled so that the ratio of CO to CO₂ is between 1:1 and 20:1. In addition, any sources of water

vapor or hydrogen are eliminated; the presence of hydrogen is thought to retard annealing, and it produces excessive decarburization of casting surfaces. Proper control of the gas atmosphere is important for avoiding an undesirable surface structure. A high ratio of CO to CO₂ retains a high level of combined carbon on the surface of the casting and produces a pearlitic rim, or picture frame, on a ferritic malleable iron part. A low ratio of CO to CO₂ permits excessive decarburization, which forms a ferritic skin on the casting with an underlying rim of pearlite. The latter condition is produced when a significant portion of the subsurface metal is decarburized to the degree that no temper carbon nodules can be developed during first-stage annealing. When this occurs, the dissolved carbon cannot precipitate from the austenite, except as the cementite plates in pearlite.

Control of Nodule Count. Proper annealing in short-term cycles and the attainment of high levels of casting quality require that controlled distribution of graphite particles be obtained during first-stage heat treatment. With low nodule count (few graphite particles per unit area or volume), mechanical properties are reduced from optimum, and second-stage annealing time is unnecessarily long because of long diffusion distances. Excessive nodule count is also undesirable, because graphite particles may become aligned in a configuration corresponding to the boundaries of the original primary cementite. In martensitic malleable iron, very high nodule counts are sometimes associated with low hardenability and nonuniform tempering. Generally, a nodule count of 80 to 150 discrete graphites particles per square millimeter of a photomicrograph magnified at 100× appears to be optimum. This produces random particle distribution, with short distances between the graphite particles.

Temper carbon is formed predominantly at the interface between primary carbide and saturated austenite at the first-stage annealing temperature, with growth around the nuclei taking place by a reaction involving diffusion and carbide decomposition. Although new nuclei undoubtedly form at the interfaces during holding at the first-stage annealing temperature, nucleation and graphitization are accelerated by the presence of nuclei that are created by appropriate melting practice. High silicon and carbon contents promote nucleation and graphitization, but these elements must be restricted to certain maximum levels because of the necessity that the iron solidify white.

Malleable Iron

Types and Properties of Malleable Iron

There are two basic types of malleable iron: blackheart and whiteheart. Blackheart malleable iron is the only type produced in North America and is the most widely used throughout the world. Whiteheart malleable iron is the older type and is essentially decarburized throughout in an extended heat treatment of white iron. This article considers only the blackheart type.

Malleable iron, like medium-carbon steel, can be heat treated to produce a wide variety of mechanical properties (Table 2). The different grades and mechanical properties are essentially the result of the matrix microstructure, which may be a matrix of ferrite, pearlite, tempered pearlite, bainite, tempered martensite, or a combination of these (all containing nodules of temper carbon). This matrix microstructure is the dominant factor influencing the mechanical properties. Other less significant factors include nodular count and the amount and compactness of the graphite (Ref 1). A higher nodular count may slightly decrease the tensile and

yield strengths (Ref 3) as well as ductility (Ref 4). More graphite or a less compact form of graphite also tends to decrease strength (Ref 1).

The different microstructures of malleable irons are determined and controlled by variations in heat treatment and/or composition. Table 3, for example, lists various types of malleable irons used in automotive applications according to heat treatment and microstructure. The range of compositions for a ferritic or pearlitic microstructure is given in Table 1.

Because the mechanical properties of malleable iron are dominated by matrix microstructure, the mechanical properties may relate quite well to the relative hardness levels of different matrix microstructures. This general effect of microstructure on malleable irons is similar to that of many other steels and irons. The softer ferritic matrix provides maximum ductility with lower strength, while increasing the amount of pearlite increases hardness and strength but decreases ductility. Martensite provides further increases in hardness and strength but with additional decreases in ductility.

The mechanical properties of pearlitic and martensitic malleable irons are closely related to hardness, as discussed in "Mechanical Properties" in the section "Pearlitic and Martensitic Malleable Irons" in this article. Therefore, grades of malleable irons are dependably specified by hardness and microstructure in ASTM A 602 and SAE J158 (Table 3). Malleable irons are also classified according to microstructure and minimum tensile properties (Table 4).

Table 2 summarizes some of the mechanical properties of the malleable irons listed in Tables 3 and 4. Additional information on the properties and heat treatment of ferritic, pearlitic, and martensitic malleable irons is provided in the following sections.

Ferritic Malleable Iron

The microstructure of ferritic malleable iron is shown in Fig. 2. A satisfactory structure consists of temper carbon in a matrix of ferrite. There should be no flake graphite and essentially no combined carbon in ferritic malleable iron. Because ferritic malleable iron consists of only ferrite and temper carbon, the properties of ferritic malleable castings depend on the quantity, size, shape, and distribution of temper carbon and on the composition of the ferrite.

Fig. 2 Structure of annealed ferritic malleable iron showing temper carbon in ferrite. 100×

Heat Treatment. Ferritic malleable iron requires a two-stage annealing cycle. The first stage converts primary carbides to temper carbon, and the second stage converts the carbon dissolved in austenite at the first-stage annealing temperature to temper carbon and ferrite.

After first-stage annealing, the castings are cooled as rapidly as practical to 740 to 760 °C (1360 to 1400 °F) in preparation for second-stage annealing. The fast cooling step requires 1 to 6 h, depending on the equipment used. Castings are then cooled slowly at a rate of about 3 to 10 °C (5 to 20 °F) per hour. During cooling, the carbon dissolved in the austenite is converted to graphite and deposited on the existing particles of temper carbon. This results in a fully ferritic matrix.

Composites. Fully annealed ferritic malleable iron castings contain 2.00 to 2.70% graphite carbon by weight, which is equivalent to about 6 to 8% by volume. Because the graphite carbon contributes nothing to the strength of the castings, those with the lesser amount of graphite are somewhat stronger and more ductile than those containing the greater amount (assuming equal size and distribution of graphite particles). Elements such as silicon and manganese in solid solution in the ferritic matrix contribute to the strength and reduce the elongation of the ferrite. Therefore, by varying base metal composition, slightly different strength levels can be obtained in a fully annealed ferritic product.

The mechanical properties that are most important for design purposes are tensile strength, yield strength, modulus of elasticity, fatigue strength, and impact strength. Hardness can be considered an approximate indicator that the ferritizing anneal was complete. The hardness of ferritic malleable iron almost always ranges from 110 to 156 HB and is influenced by the total carbon and silicon contents.

The tensile properties of ferritic malleable iron are usually measured on unmachined test bars. These properties are listed in Table 2.

The fatigue limit of unnotched ferritic malleable iron is about 50 or 60% of the tensile strength (see the two unnotched plots in Fig. 3). Figure 3 also plots the fatigue properties with notched specimens. Notch radius generally has little effect on fatigue strength, but fatigue strength decreases with increasing notch depth (Fig. 4).

Fig. 3 Fatigue properties of two ferritic malleable irons (25 mm, or 1 in., diam bars) from bending fatigue tests on notched and unnotched specimens. The unnotched fatigue limit is about 200 MPa (29 ksi) for the iron with a

342 MPa (50 ksi) tensile strength and about 185 MPa (27 ksi) for the iron with a 293 MPa (42.5 ksi) tensile strength. Source: Ref 5

Fig. 4 Effects of notch radius and notch depth on the fatigue strength of ferritic malleable iron

The modulus of elasticity in tension is about 170 GPa (25×10^6 psi). The modulus in compression ranges from 150 to 170 GPa (22×10^6 to 25×10^6 psi); in torsion, from 65 to 75 GPa (9.5×10^6 to 11×10^6 psi).

Fracture Toughness. Because brittle fractures are most likely to occur at high strain rates, at low temperatures, and with a high restraint on metal deformation, notch tests such as the Charpy V-notch test are conducted over a range of test temperatures to establish the toughness behavior and the temperature range of transition from ductile to a brittle fracture. Figure 5 illustrates the behavior of ferritic malleable iron and several types of pearlitic malleable iron in the Charpy V-notch test. This shows that ferritic malleable iron has a higher upper shelf energy and a lower transition temperature to a brittle fracture than pearlitic malleable iron. Additional information on the fracture toughness of malleable irons is available in the section "Pearlitic and Martensitic Malleable Iron" in this article.

Fig. 5 Charpy V-notch transition curves for ferritic and pearlitic malleable irons. Source: Ref 1

Elevated-Temperature Properties. Short-term, high-temperature tensile properties typically show no significant change to 370 °C (700 °F). The short-term tensile properties of two ferritic malleable irons are shown in Fig. 6. Sustained-load stress-rupture data from 425 to 650 °C (800 to 1200 °F) are given in Fig. 7.

The solid lines are curves determined by the method of least squares from the existing data and are least squares fit to the data. The dashed lines define the 90% symmetrical tolerance interval. The lower dashed curve defines time and load for 95% survivors, and the upper dashed curve is the boundary for 5% survivors. Normal distribution is assumed. Source: Ref 6

The corrosion resistance of ferritic malleable iron is increased by the addition of copper, usually about 1%, in certain applications, for example, conveyor buckets, bridge castings, pipe fittings, railroad switch stands, and freight-car hardware. One important use for copper-bearing ferritic malleable iron is chain links. Ferritic malleable iron can be galvanized to provide added protection. The effects of copper on the corrosion resistance

of ferrous alloys are documented in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Welding and Brazing. Welding of ferritic malleable iron almost always produces brittle white iron in the weld zone and the portion of the heat-affected zone immediately adjacent to the weld zone. During welding, temper carbon is dissolved, and upon cooling it is reprecipitated as carbide rather than graphite. In some cases, welding with a cast iron electrode may produce a brittle gray iron weld zone. The loss of ductility due to welding may not be serious in some applications. However, welding is usually not recommended unless the castings are subsequently annealed to convert the carbide to temper carbon and ferrite. Ferritic malleable iron can be fusion welded to steel without subsequent annealing if a completely decarburized zone as deep as the normal heat-affected zone is produced at the faying surface of the malleable iron part before welding. Silver brazing and tin-lead soldering can be satisfactorily used.

Pearlitic and Martensitic Malleable Iron

Pearlitic and martensitic-pearlitic malleable irons can be produced with a wide variety of mechanical properties, depending on heat treatment, alloying, and melting practices. The lower-strength pearlitic malleable irons are often produced by air cooling the casting after the first-stage anneal, while the higher-strength (pearlitic-martensitic) malleable irons are made by liquid quenching after the first-stage anneal. These two methods are discussed in the sections "Heat Treatment for Pearlitic Malleable Irons" and "Heat Treatment for Pearlitic-Martensitic Malleable Irons" in this article.

Given suitable heat treatment facilities, air cooling or liquid quenching after the first-stage anneal is generally the most economical heat treatment for producing pearlitic or martensitic-pearlitic malleable irons, respectively. Otherwise, ferritic iron produced from two-stage annealing is reheated to the austenite temperature and then quenched. This method is discussed in the section "Rehardened-and-Tempered Malleable Iron" in this article. Finally, the lower-strength pearlitic malleable irons can also be produced by alloying and a two-stage annealing process. The last method involves alloying during the melting process so that the carbides dissolved in the austenite do not decompose during cooling from the first-stage annealing temperature.

Heat Treatment for Pearlitic Malleable Irons. In the production of pearlitic malleable iron, the first-stage anneal is identical to that used for ferritic malleable iron. After this, however, the process changes. Some foundries then slowly cool the castings to about 870 °C (1600 °F). During cooling, the combined carbon content of the austenite is reduced to about 0.75%, and the castings are then air cooled. Air cooling is accelerated by an air blast to avoid the formation of ferrite envelopes around the temper carbon particles (bull's-eye structure) and to produce a fine pearlitic matrix (Fig. 8). The castings are then tempered to specification, or they are reheated to reaustenitize at about 870 °C (1600 °F), oil quenched, and tempered to specification. Large foundries usually eliminate the reaustenitizing step and quench the castings in oil directly from the first-stage annealing furnace after stabilizing the temperature at 845 to 870 °C (1550 to 1600 °F).

Fig. 8 Structure of air-cooled pearlitic malleable iron. (a) Slowly air cooled. 400×. (b) Cooled in an air blast.

The rate of cooling after first-stage annealing is important in the formation of a uniform pearlitic matrix in the air-cooled casting, because slow rates permit partial decomposition of carbon in the immediate vicinity of the temper carbon nodules, which results in the formation of films of ferrite around the temper carbon (bull's-eye structure). When the extent of these films becomes excessive, a carbon gradient is developed in the matrix. Air cooling is usually done at a rate not less than about 80 °C (150 °F) per minute.

Air-quenched malleable iron castings have hardnesses ranging from 269 to 321 HB, depending on casting size and cooling rate. Such castings can be tempered immediately after air cooling to obtain pearlitic malleable iron with a hardness of 241 HB or less.

Heat Treatment for Pearlitic-Martensitic Malleable Irons. High-strength malleable iron castings of uniformly high quality are usually produced by liquid quenching and tempering. The most economical procedure is direct quenching after first-stage annealing. In this procedure, the castings are cooled in the furnace to the quenching temperature of 845 to 870 °C (1550 to 1600 °F) and held for 15 to 30 min to homogenize the matrix. The castings are then quenched in agitated oil to develop a matrix microstructure of martensite having a hardness of 415 to 601 HB. Finally, the castings are tempered at an appropriate temperature between 590 and 725 °C (1100 and 1340 °F) to develop the specified mechanical properties. The final microstructure consists of tempered martensite plus temper carbon, as shown in Fig. 9. In heavy sections, higher-temperature transformation products such as fine pearlite are usually present.

Fig. 9 Structure of oil-quenched and tempered martensitic malleable iron. (a) 163 HB. 500×. (b) 179 HB. 500×. (c) 207 HB. 500×. (d) 229 HB. 500×

Some foundries produce high-strength malleable iron by an alternative procedure in which the castings are forced-air cooled after first-stage annealing, retaining about 0.75% C as pearlite. The castings are then reheated at 840 to 870 °C (1545 to 1600 °F) for 15 to 30 min, followed by quenching and tempering as above for the direct-quench process.

Rehardened-and-tempered malleable iron can also be produced from fully annealed ferritic malleable iron with a slight variation in the heat treatment used for arrested-annealed (air-quenched) malleable. The matrix of fully annealed ferritic malleable iron is essentially carbon free, but can be recarburized by heating at 840 to 870

°C (1545 to 1600 °F) for 1 h. In general, the combined carbon content of the matrix produced by this procedure is slightly lower than that of arrested-annealed pearlitic malleable iron, and the final tempering temperatures required for the development of specific hardnesses are lower. Rehardened malleable iron made from ferritic malleable may not be capable of meeting certain specifications.

Tempering times of 2 h or more after either air cooling or liquid quenching are needed for uniformity. In general, the control of final hardness of the castings is precise, with process limitations approximately the same as those encountered in the heat treatment of medium- or high-carbon steels. This is particularly true when specifications require hardnesses of 241 to 321 HB where control limits of ± 0.2 mm Brinell diameter can be maintained with ease. At lower hardnesses, a wider process control limit is required because of certain unique characteristics of the pearlitic malleable iron microstructure.

The mechanical properties of pearlitic and martensitic malleable iron vary in a substantially linear relationship with Brinell hardness (Fig. 10 and 11). In the low-hardness ranges, below about 207 HB, the properties of air-quenched and tempered pearlitic malleable are essentially the same as those of oil-quenched tempered martensitic malleable. This is because attaining the low hardnesses requires considerable coarsening of the matrix carbides and partial second-stage graphitization. Either an air-quenched pearlitic structure or an oil-quenched martensitic structure can be coarsened and decarburized to meet this hardness requirement.

Fig. 10 Relationships of tensile properties to Brinell hardness for pearlitic malleable irons from two foundries. The mechanical properties of these irons vary in a substantially linear relationship with Brinell hardness, and in the low-hardness ranges (below about 207 HB), the properties of air-quenched and tempered material are essentially the same as those produced by oil quenching and tempering.

Fig. 11 Tensile properties of pearlitic malleable iron at various hardness levels. At foundry A, the iron was made by alloying with manganese, with completion of first-stage graphitization, air cooling under air blast from 938 °C (1720 °F), and subcritical tempering for spheroidizing.

At higher hardnesses, oil-quenched and tempered malleable iron has higher yield strength and elongation than air-quenched and tempered malleable iron because of greater uniformity of matrix structure and finer distribution of carbide particles. Oil-quenched quenched and tempered pearlitic malleable iron is produced commercially to hardnesses as high as 321 HB, while the maximum hardness for high-production air-quenched

and tempered pearlitic malleable iron is about 255 HB. The lower maximum hardness is applied to the air-quenched material because:

- Hardness upon air quenching normally does not exceed 321 HB and may be as low as 269 HB; therefore, attempts to temper to a hardness range above 255 HB produce nonuniform hardness and make the process control limits excessive
- Very little structural alteration occurs during the tempering heat treatment to a higher hardness, and the resulting structure is more difficult to machine than an oil-quenched and tempered structure at the same hardness
- There is only a slight improvement in other mechanical properties with increased hardness above 255 HB

Because of these considerations, applications for air-quenched and tempered pearlitic malleable iron are usually those requiring moderate strength levels, while the higher-strength applications need the oil-quenched and tempered material.

The tensile properties of pearlitic malleable irons are normally measured on machined test bars. These properties are listed in Table 2.

The compressive strength of malleable irons is seldom determined, because failure in compression seldom occurs. As a result of the decreased influence of the graphite nodules and the delayed onset of plastic deformation in compression, compressive yield strengths are characteristically slightly higher than tensile yield strengths for the same hardness (Ref 1, 7).

Shear and Torsional Strength. The shear strength of ferritic malleable irons is approximately 80% of the tensile strength, and for pearlitic iron it ranges from 70 to 90% of the tensile strength (Ref 7). The ultimate torsional strength of ferritic malleable irons is about 90% of the ultimate tensile strength. The yield strength in torsion is 75 to 80% of the value in tension (Ref 1). Torsional strengths for pearlitic grades are approximately equal to, or slightly less than, the tensile strength of the material. Yield strengths in torsion vary from 70 to 75% of the tensile yield strength (Ref 7). The characteristic torsional properties of ferritic and pearlitic malleable irons are related to hardness, as shown in Fig. 12. As expected, the amount of twist before failure decreases with increasing strength.

Fig. 12 Torsional properties of pearlitic malleable irons in relation to hardness. Source: Ref 1

The modulus of elasticity in tension of pearlitic malleable iron is 176 to 193 GPa (25.5×10^6 to 28.0×10^6 psi). For automobile crankshafts, the modulus is important and must be determined with greater precision.

Fracture Toughness. The results of Charpy V-notch tests on pearlitic malleable iron are presented in Fig. 5. The fracture toughness of ferritic and pearlitic malleable irons has not been widely studied, but one researcher has estimated K_{Ic} values for these materials by using a J -integral approach (Ref 8). Table 5 summarizes the fracture toughness values obtained for the various grades of malleable iron at various temperatures. All of the materials exhibited stable crack extension prior to fracture for 25 mm (1 in.) wide compact-tension specimens.

Table 5 Fracture toughness of malleable irons

Malleable iron grade	Test temperature		Yield strength		K_{Ic}	
	°C	°F	MPa	ksi	MPa \sqrt{m}	ksi \sqrt{in}
Ferritic						
M3210	24	75	230	33	44	40
	-19	-3	240	35	42	38

	-59	-74	250	36	44	40
Pearlitic						
M4504 (normalized)	24	75	360	52	55	50
	-19	-2	380	55	48	44

	-58	-72	570	83	40	36

Source: Ref 7

As for ductile irons, fracture toughness testing indicates that malleable irons possess considerably more toughness than is indicated by Charpy impact toughness results. Although the fracture toughness values for pearlitic grades are similar to those obtained for ferritic grades, the higher yield strengths of the pearlitic grades indicate that their critical flaw sizes, which are proportional to $(K_{Ic}/\sigma_y)^2$, are less than those of the ferritic grades of malleable iron. Detailed information on the principles of fracture toughness and the nomenclature associated with fracture, mechanics studies is available in the Section "Fracture Mechanics" and the article "Dynamic Fracture Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Mechanical Properties at Elevated Temperatures. Figure 13 shows the short-term high-temperature tensile strength of five pearlitic malleable irons and three martensitic malleable irons. Generally, the room-temperature tensile strengths are related to hardness, while the tensile strengths at temperatures above about 450 °C (840 °F) exhibit asymptotic behavior.

(a)

(b)

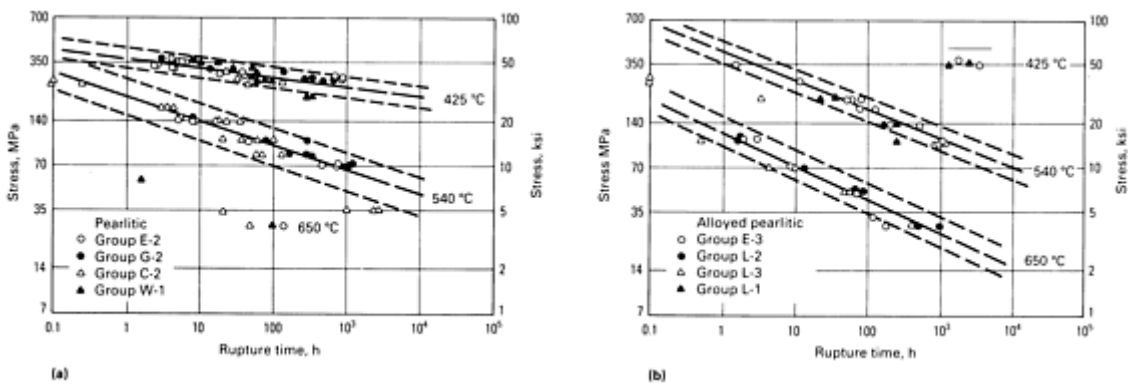

(c)

Fig. 13 Short-term elevated-temperature tensile strengths of (a) partially spheroidized pearlitic malleable irons produced by air cooling after the temper carbon anneal, (b) finely spheroidized pearlitic malleable irons produced by oil quenching after the temper carbon anneal, and (c) oil-quenched and tempered martensitic malleable irons. The two martensitic malleable irons with hardnesses of 228 HB were reheated (reaustenitized) after the temper carbon anneal (18 h soak at 950 °C, or 1740 °F) and then oil quenched. The 263 HB iron was oil quenched from 840 °C (1545 °F) after an anneal of 9.5 h at 950 °C (1740 °F). After oil quenching, all three martensitic irons were tempered. Source: Ref 5

Figure 13 also illustrates two exceptions of the general relationship between hardness and room-temperature tensile strength. The first exception is that the 230 HB pearlitic malleable iron in Fig. 13(a) has a slightly higher room-temperature tensile strength than the 233 HB pearlitic malleable iron in Fig. 13(b). This difference, however, diminishes at temperatures above 100 °C (210 °F).

The second exception is the difference in tensile strength for two malleable irons of the same hardness (Fig. 13c). This variation is perhaps attributable to the differences in heat treatment. Both of the martensitic malleable irons with hardnesses of 228 HB were annealed, cooled, reheated (reaustenitized), and then oil quenched. Before the reheat, however, the two irons underwent different cooling procedures. The 228 HB iron with the higher strength was air cooled from 870 °C (1600 °F) after the temper carbon anneal (18 h soak at 950 °C, or 1740 °F), while the 228 HB martensitic iron with the lower strength was stabilized at 780 °C (1435 °F) for 6 h and then slow cooled to 700 °C (1290 °F) before reheating.

Sustained-load stress-rupture data for eight grades of pearlitic malleable iron are shown in Fig. 14. Results of high-temperature Charpy V-notch tests showing the effect of hardness on impact energy are given in Fig. 15.

Fig. 15 Charpy V-notch impact energy of one heat of air-quenched and tempered pearlitic malleable iron

The **unnotched fatigue limits** of tempered pearlitic malleable irons (air cooled or oil quenched) are about 40 to 50% of tensile strength. Tempered martensitic malleable irons (oil quenched) have an unnotched fatigue limit of about 35 to 40% of tensile strength (Fig. 16). The V-notched fatigue limits of the three irons in Fig. 16 ranged from 110 to 125 MPa (16 to 18 ksi) (Ref 5). Oil-quenched and tempered martensitic iron usually has a higher fatigue ratio than pearlitic iron made by the arrested anneal method.

Fig. 16 Fatigue properties of three oil-quenched and tempered martensitic malleable irons from bending fatigue tests on unnotched 25 mm (1 in.) diam bars. Source: Ref 5

Wear Resistance. Because of its structure and hardness, pearlitic and martensitic malleable irons have excellent wear resistance. In some moving parts where bushings are normally inserted at pivot points, heat-treated malleable iron has proved to be so wear resistant that the bushings have been eliminated. One example of this is the rocker arm for an overhead-valve automotive engine.

Welding and Brazing. Welding of pearlitic or martensitic malleable iron is difficult because the high temperatures used can cause the formation of a brittle layer of graphite-free white iron. Pearlitic and martensitic malleable iron can be successfully welded if the surface to be welded has been heavily decarburized.

Pearlitic or malleable iron can be brazed by various commercial processes. One application is the induction silver brazing of a pearlitic malleable casting and a steel shaft to form a planetary output shaft for an automotive transmission. In another automotive application, two steel shafts are induction copper brazed to a pearlitic malleable iron shifter shaft plate.

Selective Surface Hardening. Pearlitic malleable iron can be surface hardened by either induction heating and quenching or flame heating and quenching to develop high hardness at the heat-affected surface. Considerable research has been done to determine the surface-hardening characteristics of pearlitic malleable and its capability of developing high hardness over relatively narrow surface bands. In general, little difficulty is encountered in obtaining hardnesses in the range of 55 to 60 HRC, with the depth of penetration being controlled by the rate of heating and the surface temperature of the part being hardened (Fig. 17).

Fig. 17 Hardness versus depth for surface-hardened pearlitic malleable irons. Curves labeled "Matrix" show hardness of the matrix, converted from microhardness tests. O, oil quenched and tempered to 207 HB before surface hardening; A, air cooled and tempered to 207 HB before surface hardening

The maximum hardness obtainable in the matrix of a properly hardened pearlitic malleable part is 67 HRC. However, conventional hardness measurements made on castings show less than 67 HRC because of the presence of the graphite particles, which are averaged into the hardness. Generally, a casting with a matrix microhardness of 67 HRC will have about 62 HRC average hardness, as measured with the standard Rockwell tester. Similarly, a Rockwell or Brinell hardness test on softer structures will show less than matrix microhardness because of the presence of graphite.

Two examples of automobile production parts hardened by induction heating are rocker arms and clutch hubs. An example of a flame-hardened pearlitic malleable iron part is a pinion spacer used to support the cup of a roller bearing. To preclude service failures, the ends of the pinion spacer are flame hardened to a depth of about 2.3 mm ($\frac{3}{32}$ in.).

Malleable iron can be carburized, carbonitrided, or nitrided to produce a surface with improved wear resistance. In addition, heat treatments such as austempering have been used in specialized applications.

Damping Capacity

The good damping capacity and fatigue strength of malleable irons are useful for long service in highly stressed parts. Figure 18 compares the damping capacity of malleable irons to that of steels. The production of high internal stresses by quenching malleable iron can double the damping capacity, which is then gradually reduced as tempering relieves residual stresses (Ref 1).

Fig. 18 Torsional damping capacity of malleable irons compared to steel. Source: Ref 1

Malleable Iron

Applications

Malleable iron castings are often selected because the material has excellent machinability in addition to significant ductility. In other applications, malleable iron is chosen because it combines castability with good toughness and machinability. Malleable iron is often chosen because of shock resistance alone. Tables 3 and 4 list some of the typical applications of malleable iron castings.

The requirement that any iron produced for conversion to malleable iron must solidify white places definite section thickness limitations on the malleable iron industry. Thick metal sections can be produced by melting a base iron of low carbon and silicon contents or by alloying the molten iron with a carbide stabilizer. However, when carbon and silicon are maintained at low levels, difficulty is invariably encountered in annealing, and the time required to convert primary and pearlitic carbides to temper carbon becomes excessively long. High-production foundries are usually reluctant to produce castings more than about 40 mm ($1 \frac{1}{2}$ in.) thick. Some foundries, however, routinely produce castings as thick as 100 mm (4 in.).

After heat treatment, ferritic or pearlitic malleable castings are cleaned by shotblasting, gates are removed by shearing or grinding, and, where necessary, the castings are coined or punched. Close dimensional tolerances can be maintained in ferritic malleable iron and in the lower-hardness types of pearlitic malleable iron, both of which can be easily straightened in dies. The harder pearlitic malleable irons are more difficult to press because of higher yield strength and a greater tendency toward springback after die pressing. However, even the highest-strength pearlitic malleable can be straightened to achieve good dimensional tolerances.

Automotive and associated applications of ferritic and pearlitic malleable irons include many essential parts in vehicle power trains, frames, suspensions, and wheels. A partial list includes differential carriers, differential cases, bearing caps, steering-gear housings, spring hangers, universal-joint yokes, automatic-transmission parts, rocker arms, disc brake calipers, wheel hubs, and many other miscellaneous castings. Examples are shown in Fig. 19. Ferritic and pearlitic malleable irons are also used in the railroad industry and in agricultural equipment, chain links, ordnance material, electrical pole line hardware, hand tools, and other parts requiring section thicknesses and properties obtainable in these materials.

Alloy Cast Irons

Revised by Richard B. Gundlach, Climax Research Services; and Douglas V. Doane, Consulting Metallurgist

Introduction

ALLOY CAST IRONS are considered to be those casting alloys based on the iron-carbon-silicon system that contain one or more alloying elements intentionally added to enhance one or more useful properties. The addition to the ladle of small amounts of substances (such as ferrosilicon, cerium, or magnesium) that are used to control the size, shape, and/or distribution of graphite particles is termed inoculation rather than alloying. The quantities of material used for inoculation neither change the basic composition of the solidified iron nor alter the properties of individual constituents. Alloying elements, including silicon when it exceeds about 3%, are usually added to increase the strength, hardness, hardenability, or corrosion resistance of the basic iron and are often added in quantities sufficient to affect the occurrence, properties, or distribution of constituents in the microstructure.

In gray and ductile irons, small amounts of alloying elements such as chromium, molybdenum, or nickel are used primarily to achieve high strength or to ensure the attainment of a specified minimum strength in heavy sections. Otherwise, alloying elements are used almost exclusively to enhance resistance to abrasive wear or chemical corrosion or to extend service life at elevated temperatures.

The strengthening effects of the various alloying elements in gray and ductile irons are dealt with in the articles "Gray Iron" and "Ductile Iron" in this Volume. This article discusses abrasion-resistant chilled and white irons, high-alloy corrosion-resistant irons, and medium-alloy and high-alloy heat-resistant gray and ductile irons. Table 1 lists approximate ranges of alloy content for various types of alloy cast irons covered in this article. Individual alloys within each type are made to compositions in which the actual ranges of one or more of the alloying elements span only a portion of the listed ranges; the listed ranges serve only to identify the types of alloys used in specific kinds of applications.

Table 1 Ranges of alloy content for various types of alloy cast irons

Description	Composition, wt % ^(a)									Matrix structure, as-cast ^(c)
	TC ^(b)	Mn	P	S	Si	Ni	Cr	Mo	Cu	

[illegible]

Ferritic grade	1-2.5	0.3-1.5	0.5-2.5	...	30-35	F
Austenitic grade	1-2.0	0.3-1.5	0.5-2.5	10-15	15-30	A

(a) Where a single value is given rather than a range, that value is a maximum limit.

(b) Total carbon.

(c) CP, coarse pearlite; M, martensite; A, austenite; F, ferrite.

(d) Can be produced from a malleable-iron base composition.

(e) Copper can replace all or part of the nickel.

(f) Such as Duriron, Durichlor 51, Superchlor.

(g) Such as Ni-Resist austenitic iron (ASTM A 436).

(h) Such as Ni-Resist austenitic ductile iron (ASTM A 439).

Alloy Cast Irons

Revised by Richard B. Gundlach, Climax Research Services; and Douglas V. Doane, Consulting Metallurgist

Classification of Alloy Cast Irons

Alloy cast irons can be classified as white cast irons, corrosion-resistant cast irons, and heat-resistant cast irons.

White cast irons, so named because of their characteristically white fracture surfaces, do not have any graphite in their microstructures. Instead, the carbon is present in the form of carbides, chiefly of the types Fe_3C and Cr_7C_3 . Often, complex carbides such as $(\text{Fe,Cr})_3\text{C}$ and $(\text{Cr,Fe})_7\text{C}_3$, or those containing other carbide-forming elements, are also present.

White cast irons are usually very hard, which is the single property most responsible for their excellent resistance to abrasive wear. White iron can be produced either throughout the section (chiefly by adjusting the composition) or only partly inward from the surface (chiefly by casting against a chill). The latter iron is sometimes referred to as chilled iron to distinguish it from iron that is white throughout.

Chilled iron castings are produced by casting the molten metal against a metal or graphite chill, resulting in a surface virtually free from graphitic carbon. In the production of chilled iron, the composition is selected so that only the surfaces cast against the chill will be free from graphitic carbon (Fig. 1). The more slowly cooled portions of the casting will be gray or mottled iron. The depth and hardness of the chilled portion can be controlled by adjusting the composition of the metal, the extent of inoculation, and the pouring temperature.

Fig. 1 Fracture surface of as-cast chilled iron. White, mottled, and gray portions are shown at full size, top to bottom.

White iron is a cast iron virtually free from graphitic carbon because of selected chemical composition. The composition is chosen so that, for the desired section size, graphite does not form as the casting solidifies. The hardness of white iron castings can be controlled by further adjustment of composition.

The main difference in microstructure between chilled iron and white iron is that chilled iron is fine grained and exhibits directionality perpendicular to the chilled face, while white iron is ordinarily coarse grained, randomly oriented, and white throughout, even in relatively heavy sections. (Fine-grain white iron can be produced by casting a white iron composition against a chill.) This difference reflects the effect of composition difference between the two types of abrasion-resistant iron. Chilled iron is directional only because the casting, made of a composition that is ordinarily gray, has been cooled through the eutectic temperature so rapidly at one or more faces that the iron solidified white, growing inward from the chilled face. White iron, on the other hand, has a composition so low in carbon equivalent or so rich in alloy content that gray iron cannot be produced even at the relatively low rates of cooling that exist in the center of the heaviest section of the casting.

Corrosion-resistant irons derive their resistance to chemical attack chiefly from their high alloy content. Depending on which of three alloying elements--silicon, chromium, or nickel--dominates the composition, a corrosion-resistant iron can be ferritic, pearlitic, martensitic, or austenitic in its microstructure. Depending on composition, cooling rate, and inoculation practice, a corrosion-resistant iron can be white, gray, or nodular in both form and distribution of carbon.

Heat-resistant irons combine resistance to high-temperature oxidation and scaling with resistance to softening or microstructural degradation. Resistance to scaling depends chiefly on high alloy content, and resistance to softening depends on the initial microstructure plus the stability of the carbon-containing phase. Heat-resistant irons are usually ferritic or austenitic as-cast; carbon exists predominantly as graphite, either in flake or spherulitic form, which subdivides heat-resistant irons into either gray or ductile irons. There are also ferritic and austenitic white iron grades, although they are less frequently used and have no American Society for Testing and Materials (ASTM) designations.

Alloy Cast Irons

Effects of Alloying Elements

In most cast irons, it is the interaction among alloying elements (including carbon and silicon) that has the greatest effect on properties. This influence is exerted largely by effects on the amount and shape of graphitic carbon present in the casting. For example, in low-alloy cast irons, depth of chill or the tendency of the iron to be white as-cast depends greatly on the carbon equivalent, the silicon in the composition, and the state of inoculation. The addition of other elements can only modify the basic tendency established by the carbon-silicon relationship.

On the other hand, abrasion-resistant white cast irons are specifically alloyed with chromium to produce fully carbidic irons. One of the benefits of chromium is that it causes carbide, rather than graphite, to be the stable carbon-rich eutectic phase upon solidification. At higher chromium contents (10% or more), M_7C_3 carbide becomes the stable carbon-rich phase of the eutectic reaction.

In general, only small amounts of alloying elements are needed to improve depth of chill, hardness, and strength. Typical effects on depth of chill are given in Fig. 2 for the alloying elements commonly used in low to moderately alloyed cast irons. High alloy contents are needed for the most significant improvements in abrasion resistance, corrosion resistance, or elevated-temperature properties.

(a)

(b)

(c)

(d)

Fig. 2 Typical effects of alloying elements on depth of chill

Alloying elements such as nickel, chromium, and molybdenum are used, singly or in combination, to provide specific improvements in properties compared to unalloyed irons. Because the use of such elements means higher cost, the improvement in service performance must be sufficient to justify the increased cost.

Carbon. In chilled irons, the depth of chill decreases (Fig. 2c), and the hardness of the chilled zone increases, with increasing carbon content. Carbon also increases the hardness of white irons. Low-carbon white irons ($\sim 2.50\%$ C) have a hardness of about 375 HB (Fig. 3), while white irons with fairly high total carbon ($>3.50\%$ C) have a hardness as high as 600 HB. In unalloyed white irons, high total carbon is essential for high hardness and maximum wear resistance. Carbon decreases transverse breaking strength (Fig. 4) and increases brittleness. It also increases the tendency for graphite to form during solidification, especially when the silicon content is also high. As a result, it is very important to keep the silicon content low in high-carbon white irons. The normal range of carbon content for unalloyed or low-alloy white irons is about 2.2 to 3.6%. For high-chromium white irons, the normal range is from about 2.2% to the carbon content of the eutectic composition, which is about 3.5% for a 15% Cr iron and about 2.7% for a 27% Cr iron.

Fig. 3 Effect of carbon content on the hardness of low-carbon white iron

Fig. 4 Effect of total carbon on the transverse breaking strength of unalloyed white iron

The carbon content of gray and ductile alloy irons is generally somewhat higher than that of a white iron of similar alloy content. In addition, the silicon content is usually higher, so that graphite will be formed upon solidification.

Silicon is present in all cast irons. In alloy cast irons, as in other types, silicon is the chief factor that determines the carbon content of the eutectic. Increasing the silicon content lowers the carbon content of the eutectic and promotes the formation of graphite upon solidification. Therefore, the silicon content is the principal factor controlling the depth of chill in unalloyed or low-chromium chilled and white irons. This effect for relatively high carbon irons is summarized in Fig. 2(a).

In high-alloy white irons, silicon has a negative effect on hardenability; that is, it tends to promote pearlite formation in martensitic irons. However, when sufficient amounts of pearlitic-suppressing elements such as molybdenum, nickel, manganese, and chromium are present, increasing the silicon content raises the M_s temperature of the alloy, thus tending to increase both the amount of martensite and the final hardness.

The silicon content of chilled and white irons is usually between 0.3 and 2.2%. In martensitic nickel-chromium white irons, the desired silicon content is usually 0.4 to 0.9%. It is necessary to select carefully the charge constituents when melting a martensitic iron so that excessive silicon content is avoided. In particular, it is necessary to give special attention to the silicon content of the ferrochromium used in the furnace charge.

Silicon additions of 3.5 to 7% improve high-temperature properties by raising the eutectoid transformation temperature. The influence of silicon on the critical temperature is shown in Fig. 5. Elevated levels of silicon also reduce the rates of scaling and growth by forming a tight, adhering oxide scale. This occurs at silicon contents above 3.5% in ferritic irons and above 5% in 36% Ni austenitic irons. Additions of 14 to 17% (often accompanied by additions of about 5% Cr and 1% Mo) yield cast iron that is very resistant to corrosive acids, although resistance varies somewhat with acid concentration.

Fig. 5 Effect of silicon content on the α to γ transformation temperature of unalloyed steel and cast iron

containing 0.09 to 4.06% C and 0.3 to 0.6% Mn

High-silicon irons (14 to 17%) are difficult to cast and are virtually unmachinable. High-silicon irons have particularly low resistance to mechanical and thermal shock at room temperature or moderately elevated temperature. However, above about 260 °C (500 °F), the shock resistance exceeds that of ordinary gray iron.

Manganese and sulfur should be considered together in their effects on gray or white iron. Alone, either manganese or sulfur increases the depth of chill, but when one is present, addition of the other decreases the depth of chill until the residual concentration has been neutralized by the formation of manganese sulfide. Generally, sulfur is the residual element, and excess manganese can be used to increase chill depth and hardness, as shown in Fig. 2(d). Furthermore, because it promotes the formation of finer and harder pearlite, manganese is often preferred for decreasing or preventing mottling in heavy-section castings.

Manganese, in excess of the amount needed to scavenge sulfur, mildly suppresses pearlite formation. It is also a relatively strong austenite stabilizer and is normally kept below about 0.7% in martensitic white irons. In some pearlitic or ferritic alloy cast irons, up to about 1.5% Mn can be used to help ensure that specified strength levels are obtained. When manganese content exceeds about 1.5%, the strength and toughness of martensitic irons begin to drop. Abrasion resistance also drops, mainly because of austenite retention. Molten iron with a high manganese content tends to attack furnace and ladle refractories. Consequently, the use of manganese is limited in cast irons, even though it is one of the least expensive alloying elements.

The normal sulfur contents of alloy cast irons are neutralized by manganese, but the sulfur content is kept low in most alloy cast irons. In abrasion-resistant cast irons, the sulfur content should be as low as is commercially feasible, because several investigations have shown that sulfides in the microstructure degrade abrasion resistance. A sulfur content of 0.03% appears to be the maximum that can be tolerated when optimum abrasion resistance is desired.

Phosphorus is a mild graphitizer in unalloyed irons; it mildly reduces chill depth in chilled irons (Fig. 2c). In alloyed irons, the effects of phosphorus are somewhat obscure. There is some evidence that it reduces the toughness of martensitic white irons. The effect, if any, on abrasion resistance has not been conclusively proved. In heavy-section castings made from molybdenum-containing irons, high phosphorus contents are considered detrimental because they neutralize part of the deep-hardening effect of the molybdenum. It is considered desirable to keep the phosphorus content of alloy cast irons below about 0.3%, and some specifications call for less than 0.1%. In cast irons for high-temperature or chemical service, it is customary to keep the phosphorus content below 0.15%.

Chromium has three major uses in cast irons:

- To form carbides
- To impact corrosion resistance
- To stabilize the structure for high-temperature applications

Small amounts of chromium are routinely added to stabilize pearlite in gray iron, to control chill depth in chilled iron, or to ensure a graphite-free structure in white iron containing less than 1% Si. At such low percentages, usually no greater than 2 to 3%, chromium has little or no effect on hardenability, chiefly because most of the chromium is tied up in carbides. However, chromium does influence the fineness and hardness of pearlite and tends to increase the amount and hardness of the eutectic carbides. Consequently, chromium is often added to gray iron to ensure that strength requirements can be met, particularly in heavy sections. On occasion, it can be added to ductile iron for the same purpose. Also, relatively low percentages of chromium are used to improve the hardness and abrasion resistance of pearlitic white cast irons.

When the chromium content of cast iron is greater than about 10%, eutectic carbides of the M_7C_3 type are formed, rather than the M_3C type that predominates at lower chromium contents. More significantly, however, the higher chromium content causes a change in solidification pattern to a structure in which the M_7C_3 carbides are surrounded by a matrix of austenite or its transformation products. At lower chromium contents, the M_3C carbide forms the matrix. Because of the solidification characteristics, hypoeutectic irons containing M_7C_3 carbides are normally stronger and tougher than irons containing M_3C carbides.

The relatively good abrasion resistance, toughness, and corrosion resistance found in high-chromium white irons have led to the development of a series of commercial martensitic or austenitic white irons containing 12 to 28% Cr. Because much of the chromium in these irons is present in combined form as carbides, chromium is much less effective than molybdenum, nickel, manganese, or copper in suppressing the eutectoid transformation to pearlite and therefore has a lesser effect on hardenability than it has in steels. Martensitic white irons usually contain one or more of the elements molybdenum, nickel, manganese, and copper to give the required hardenability. These elements ensure that martensite will form upon cooling from above the upper transformation temperature either while the casting is cooling in the mold or during subsequent heat treatment.

It is difficult to maintain low silicon content in high-chromium irons because of the silicon introduced by high-carbon ferrochrome and other sources. Low silicon content is advantageous in that it provides for ready response to annealing and yields high hardness when the alloy is air quenched from high temperatures. High silicon content lessens response to this type of heat treatment. Although high-chromium white irons are sometimes used as-cast, their optimum properties are obtained in the heat-treated condition.

For developing resistance to the softening effect of heat and for protection against oxidation, chromium is the most effective element. It stabilizes iron carbide and therefore prevents the breakdown of carbide at elevated temperatures; 1% Cr give adequate protection against oxidation up to about 760 °C (1400 °F) in many applications. For temperatures of 760 °C (1400 °F) and above, chromium contents up to 5.5% are found in austenitic ductile irons for added oxidation resistance. For long-term oxidation resistance at elevated temperatures, white cast irons having chromium contents of 15 to 35% are employed. This percentage of chromium suppresses the formation of graphite and makes the alloy solidify as white cast iron.

High levels of chromium stabilize the ferrite phase up to the melting point; typical high-chromium ferritic irons contain 30 to 35% Cr. Austenitic grades of high-chromium irons, which have significantly higher strength at elevated temperatures, contain 10 to 15% Ni, along with 15 to 30% Cr.

Nickel is almost entirely distributed in the austenitic phase or its transformation products. Like silicon, nickel promotes graphite formation, and in white and chilled irons, this effect is usually balanced by the addition of about one part chromium for every three parts nickel in the composition. If fully white castings are desired, the amount of chromium can be increased. Some low- and medium-alloy cast irons have a ratio as low as one part chromium to 1.3 parts nickel. In high-chromium irons, the nickel content may be as high as 15% to stabilize the austenite phase.

When added to low-chromium white iron in amounts up to about 2.5%, nickel produces a harder and finer pearlite in the structure, which improves its abrasion resistance. Nickel in somewhat larger amounts--up to about 4.5%--is needed to completely suppress pearlite formation, thus ensuring that a martensitic iron results when the castings cool in their molds. This latter practice forms the basis for production of the Ni-Hard cast irons (which are usually identified in standard specification as nickel-chromium martensitic irons). With small castings such as grinding balls, which can be shaken out of the molds while still hot, air cooling from the shakeout temperature will produce the desired martensitic structure even when the nickel content is as low as 2.7%. On the other hand, an excessively high nickel content (more than about 6.5%) will so stabilize the austenite that little martensite, if any, can be formed in castings of any size. Appreciable amounts of retained austenite in Ni-Hard cast irons can be transformed to martensite by refrigerating the castings at -55 to -75 °C (-70 to -100 °F) or by using special tempering treatments.

One of the Ni-Hard family of commercial alloy white irons (type IV Ni-Hard) contains 1.0 to 2.2% Si, 5 to 7% Ni, and 7 to 11% Cr. In the as-cast condition, it has a structure of M_7C_3 eutectic carbides in a martensitic matrix. If retained austenite is present, the martensite content and hardness of the alloy can be increased by refrigeration treatment or by re-austenitizing and air cooling. Ni-Hard IV is often specified for pumps and other equipment used for handling abrasive slurries because of its combination of relatively good strength, toughness, and abrasion resistance.

Nickel is used to suppress pearlite formation in large castings of high-chromium white iron (12 to 28% Cr.) The typical amount of nickel is about 0.2 to 1.5%, and it is usually added in conjunction with molybdenum. Nickel contents higher than this range tend to excessively stabilize the austenite, leading to austenite retention. Control of composition is especially important for large castings that are intended to be martensitic, because their size dictates that they cool slowly regardless of whether they are to be used as-cast or after heat treatment.

Nickel additions of more than 12% are needed for optimum resistance to corrosion or heat. High-nickel gray or ductile irons usually contain 1 to 6% Cr and may contain as much as 10% Cu. These elements act in conjunction with the nickel to promote resistance to corrosion and scaling, especially at elevated temperatures. All types of cast iron with nickel contents above 18% are fully austenitic.

Copper in moderate amounts can be used to suppress pearlite formation in both low- and high-chromium martensitic white irons. The effect of copper is relatively mild compared to that of nickel, and because of the limited solubility of copper in austenite, copper additions probably should be limited to about 2.5% or less. This limitation means that copper cannot completely replace nickel in Ni-Hard-type irons. When added to chilled iron without chromium, copper narrows the zone of transition from white to gray iron, thus reducing the ratio of the mottled portion to the clear chilled portion.

Copper is most effective in suppressing pearlite when it is used in conjunction with about 0.5 to 2.0% Mo. The hardenability of this combination is surprisingly good, which indicates that there is a synergistic effect when copper and molybdenum are added together to cast iron. Combined additions appear to be particularly effective in the martensitic high-chromium irons. Here, copper content should be held to 1.2% or less; larger amounts tend to induce austenite retention.

Copper is used in amounts of about 3 to 10% in some high-nickel gray and ductile irons that are specified for corrosion or high-temperature service. Here, copper enhances corrosion resistance, particularly resistance to oxidation or scaling.

Molybdenum in chilled and white iron compositions is distributed between the eutectic carbides and the matrix. In graphitic irons, its main functions are to promote deep hardening and to improve high-temperature strength and corrosion resistance.

In chilled iron compositions, molybdenum additions mildly increase depth of chill (they are about one-third as effective as chromium; see Fig. 2d). The primary purpose of small additions (0.25 to 0.75%) of molybdenum to chilled iron is to improve the resistance of the chilled face to spalling, pitting, chipping, and heat checking. Molybdenum hardens and toughens the pearlitic matrix.

Where a martensitic white iron is desired for superior abrasion resistance, additions of 0.5 to 3.0% Mo effectively suppress pearlite and other high-temperature transformation products (Fig. 6). Molybdenum is even more effective when used in combination with copper, chromium, nickel, or both chromium and nickel. Molybdenum has an advantage over nickel, copper, and manganese in that it increases depth of hardening without appreciably over-stabilizing austenite, thus preventing the retention of undesirably large amounts of austenite in the final structure. Figure 6 illustrates the influence of different amounts of molybdenum on the hardenability of high-chromium white irons and shows that the hardenability (measured as the critical diameter for air hardening) increases as the ratio of chromium to carbon increases.

Fig. 6 Effect of molybdenum content on the hardenability of high-chromium white irons of different chromium-to-carbon (Cr/C) ratios

The pearlite-suppressing properties of molybdenum have been used to advantage in irons of high chromium content. White irons with 12 to 18% Cr are used for abrasion-resistant castings. The addition of 1 to 4% Mo is effective in suppressing pearlite formation, even when the castings are slowly cooled in heavy sections.

Molybdenum can replace some of the nickel in the nickel-chromium type of martensitic white irons. In heavy-section castings in which 4.5% Ni would be used, the addition of 1% Mo permits a reduction of nickel content to about 3%. In light-section castings of this type, where 3% Ni would normally be used, the addition of 1% Mo permits a reduction of nickel to 1.5%.

Molybdenum, in quantities of about 1 to 4%, is effective in enhancing corrosion resistance, especially in the presence of chlorides. In quantities of $\frac{1}{2}$ to 2%, molybdenum improves high-temperature strength and creep resistance in gray and ductile irons with ferritic or austenitic matrices. Figure 7 illustrates the influence of

molybdenum on the strength and creep resistance of high-silicon (4% Si) ferritic ductile iron at 705 °C (1300 °F).

(a)

Fig. 7 Influence of molybdenum on (a) tensile properties and (b) creep resistance of 4% Si ductile iron at 705 °C (1300 °F)

Vanadium is a potent carbide stabilizer and increases depth of chill. The magnitude of the increase of depth of chill depends on the amount of vanadium and the composition of the iron as well as on section size and

conditions of casting. The powerful chilling effect of vanadium in thin sections can be balanced by additions of nickel or copper, by a large increase in carbon or silicon, or both. In addition to its carbide-stabilizing influence, vanadium in amounts of 0.10 to 0.50% refines the structure of the chill and minimizes coarse columnar grain structure. Because of its strong carbide-forming tendency, vanadium is rarely used in gray or ductile irons for corrosion or elevated-temperature service.

Alloy Cast Irons

Effects of Inoculants

Certain elements, when added in minute amounts in the pouring ladle, have relatively strong effects on the size, shape, and distribution of graphite in graphitic cast irons. Other elements are equally powerful in stabilizing carbides. These elements, called inoculants, appear to act more as catalysts than as participants in the reactions.

The main graphitizing inoculant is ferrosilicon, which is often added in detectable amounts (several kilograms per tonne) as a final adjustment of carbon equivalent in gray or ductile irons. In ductile irons, it is essential that the graphite be present in the final structure as nodules (spherulites) rather than as flakes. Magnesium, cerium, rare-earth elements, and certain proprietary substances are added to the molten iron just before pouring to induce the graphite to form in nodules of the desired size and distribution.

In white irons, tellurium, bismuth, and sometimes vanadium are the principal carbide-inducing inoculants. Tellurium is extremely potent; an addition of only about 5 g/t (5 ppm) is often sufficient. Tellurium has one major drawback. It has been found to cause tellurium halitosis in foundry workers exposed to even minute traces of its fumes; therefore, its use as an inoculant has been discouraged and sometimes prohibited.

Bismuth, in amounts of 50 to 100 g/t (50 to 100 ppm), effectively suppresses graphite formation in unalloyed or low-alloy white iron. In particular, bismuth is used in the low-carbon compositions destined for malleabilizing heat treatment. It has been reported that bismuth produces a fine-grain microstructure free from spiking, a condition that is sometimes preferred in abrasion-resistant white irons.

Vanadium, in amounts up to 0.5%, is sometimes considered useful as a carbide stabilizer and grain refiner in white or chilled irons. Nitrogen- and boron-containing ferroalloys have also been used as inoculants with reported beneficial effects. In general, however, the economic usefulness of inoculants in abrasion-resistant white irons has been inconsistent and remains unproved. Inoculants other than appropriate graphitizing or nodularizing agents are used rarely, if ever, in high-alloy corrosion-resistant or heat-resistant irons.

Alloy Cast Irons

Revised by Richard B. Gundlach, Climax Research Services; and Douglas V. Doane, Consulting Metallurgist

Abrasion-Resistant Cast Irons

It should be presumed that parts subjected to abrasion will wear out and will therefore need to be replaced from time to time. Also, for many applications, there will be one or more types of relatively low-cost material that will have adequate wear resistance and one or more types of higher-cost material that will have measurably superior wear resistance. For both situations, the ratio of wear rate to replacement cost should be evaluated; this ratio can be a very effective means of evaluating the most economical use of materials. It is often more economical to use a less wear-resistant material and replace it more often. However, in some cases, such as

when frequent occurrences of downtime cannot be tolerated, economy is less important than service life. Total cost-effectiveness must take into account the actual cost of materials, heat treatment, time for removal of worn parts and insertion of new parts, and other production time lost.

In general, chilled iron and unalloyed white iron are less expensive than alloy irons; they are also less wear resistant. However, the abrasion resistance of chilled or unalloyed white iron is entirely adequate for many applications. It is only when a clear performance advantage can be proved that alloy cast irons will show an economic advantage over unalloyed irons. For example, in a 1-year test in a mill for grinding cement clinker, grinding balls made of martensitic nickel-chromium white iron had to be replaced only about one-fifth as often as forged and hardened alloy steel balls. In another test of various parts in a brick-making plant, martensitic nickel-chromium white iron was found to last three to four times as long as unalloyed white iron, in terms of both tonnage handled and lifetime in days. In both cases, martensitic nickel-chromium white iron showed a clear economic advantage as well as a clear performance advantage over the alternative materials.

Typical Compositions. The first two lines of Table 1 list the composition ranges for the typical commercial unalloyed and low-alloy grades of white and chilled irons used for abrasion-resistant castings. These are nominally classed as pearlitic white irons. Historically, most of the early white iron castings produced for abrasion resistance were cast from low-carbon, 1.0 to 1.6% Si unalloyed compositions, which were also used for malleable iron castings. As changes have occurred in demand and specific uses, the trend has been to produce a more abrasion-resistant 2.8 to 3.6% C, low-silicon grade, which is usually alloyed with chromium to suppress graphite and to increase the fineness and hardness of the pearlite. Other alloying elements such as nickel, molybdenum, copper, and manganese are used primarily to increase hardenability in order to obtain austenitic or martensitic structures.

Martensitic white irons have largely displaced pearlitic white irons for making many types of abrasion-resistant castings, with the possible exception of chilled iron rolls and grinding balls. Although martensitic white irons cost more than pearlitic irons, their much superior abrasion resistance, combined with the increasing costs of all castings, makes martensitic alloy white irons economically attractive. The better strength and toughness of martensitic irons favor their use, and the trend toward replacing cupola melting with electric furnace melting makes martensitic white irons relatively easy to produce.

Table 2 lists the composition ranges of commercial martensitic white cast irons. The iron alloys of class I are designed to be largely martensitic as-cast; the only heat treatment commonly applied is tempering.

Table 2 Chemical composition of standard martensitic white cast irons

Certain specific compositions of alloys II-B, II-C, II-D, and II-E are covered by U.S. Patent 3,410,682.

- (a) Where a single value is given rather than a range, that value is a maximum limit.
- (b) Total carbon.

The iron alloys of classes II and III are either pearlitic or austenitic as-cast, except in slow-cooling heavy sections, which may be partially martensitic. The iron alloys of classes II and III are usually heat treated as described below. There are several situations in which the abrasion resistance of the as-cast austenitic casting is very good; no heat treatment is applied in such cases.

Heat Treatment. Various high- and low-temperature heat treatments can be used to improve the properties of white and chilled iron castings. For the unalloyed or low-chromium pearlite white irons, heat treatment is performed primarily to relieve the internal stresses that develop in the castings as they cool in their molds. Generally, such heat treatments are used only on large castings such as mill rolls and chilled iron car wheels. Temperatures up to about 705 °C (1300 °F) can be used without severely reducing abrasion resistance. In some cases, the castings can be removed from their molds above the pearlitic-formation temperature and can then be isothermally transformed to pearlite (or to ferrite and carbide) in an annealing furnace. As the tempering or annealing temperature is increased, the time at temperature must be reduced to prevent graphitization. Results of reheating tests on unalloyed chilled iron with a composition of 3.25 to 3.60% C, 0.50 to 0.55% Si, 0.55 to 0.60% Mn, 0.33% P, and 0.13% S are given in Fig. 8.

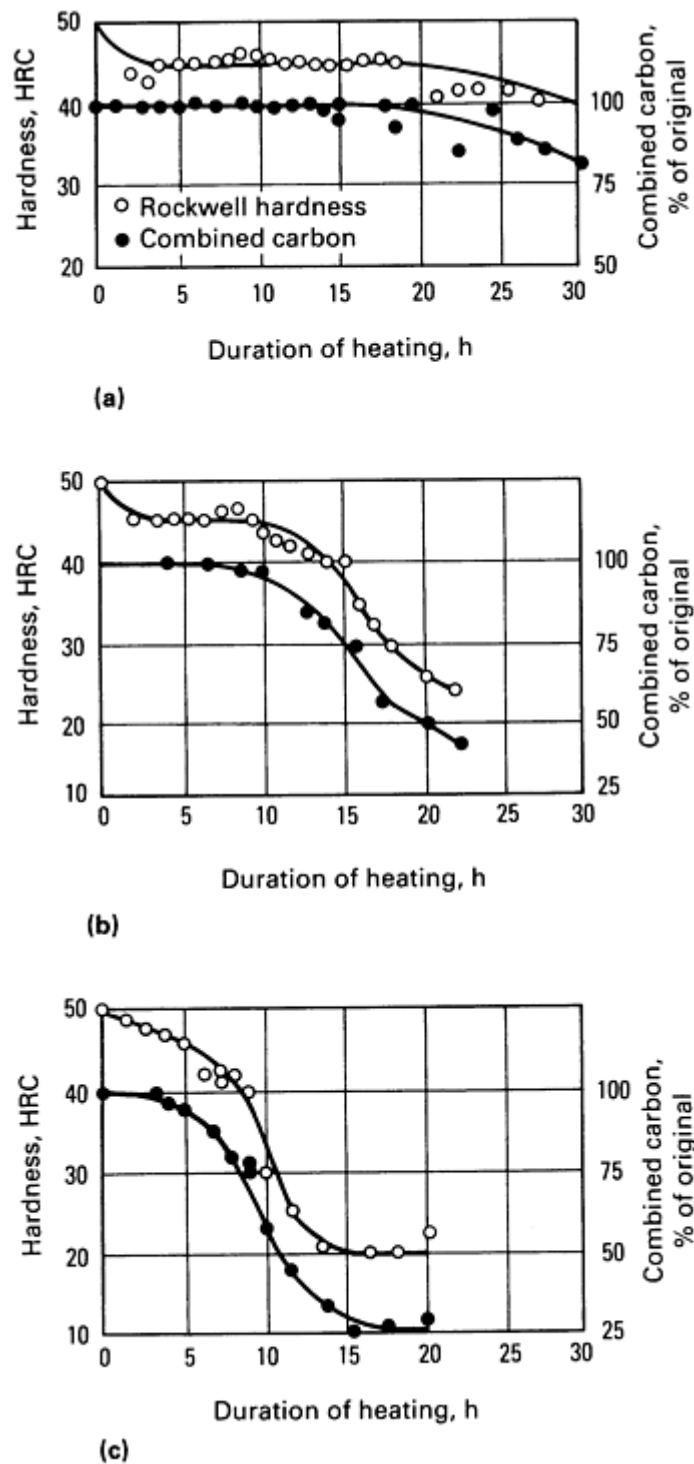

Fig. 8 Effect of annealing on hardness and combined carbon content in chilled iron. Effect of heating at (a) 815 °C (1500 °F), (b) 845 °C (1550 °F), (c) 870 °C (1600 °F) on hardness and combined carbon content of chilled portion of a chilled iron casting. See text for composition.

Residual stresses in large castings result from volume changes during the transformation of austenite and during subsequent cooling of the casting to room temperature. Because these volume changes may not occur simultaneously in each part of the casting, they tend to set up residual stresses, which may be very high and may therefore cause the casting to crack in the foundry or in service. A quantitative indication of changes in expansion coefficient and specific heat with changes in temperature is shown in Fig. 9.

Fig. 9 Thermal expansion (a) and specific heat (b) of white iron

The nickel-chromium martensitic white irons, containing up to about 7% Ni and 11% Cr, are usually put into service after only a low-temperature heat treatment at 230 to 290 °C (450 to 550 °F) to temper the martensite and to increase toughness. If retained austenite is present and the iron therefore has less than optimum hardness, a subzero treatment down to liquid nitrogen temperature can be employed to transform much of the retained austenite to martensite. Subzero treatment substantially raises the hardness, often as much as 100 Brinell points. Following subzero treatment, the castings are almost always tempered at 230 to 260 °C (450 to 500 °F). The austenite-martensite microstructures produced in nickel-alloyed irons are often desirable for their intrinsic toughness.

It is possible to transform additional retained austenite by heat treating nickel-chromium white irons at about 730 °C (1350 °F). Such a treatment decreases matrix carbon and therefore raises the M_s temperature. However, high-temperature treatments are usually less desirable than subzero treatments because the former are more costly and more likely to induce cracking due to transformation stresses.

The high-chromium martensitic white irons (>12% Cr) must be subjected to a high-temperature heat treatment to develop full hardness. They can be annealed to soften them for machining, then hardened to develop the required abrasion resistance. Because of their high chromium content, there is no likelihood of graphitization while the castings are held at the re-austenitizing temperature.

The usual re-austenitizing temperature for high-chromium irons ranges from about 955 °C (1750 °F) for a 15Cr-Mo iron to about 1065 °C (1950 °F) for a 27% Cr iron. An appreciable holding time (3 to 4 h minimum) at temperature is usually mandatory to permit precipitation of dispersed secondary carbide particles in the austenite. This lowers the amount of carbon dissolved in the austenite to a level that permits transformation to martensite during cooling to room temperature. Air quenching is usually used, although small, simply shaped castings can be quenched in oil or molten salt without producing quench cracks. Following quenching, it is advisable to stress relieve (temper) the castings at about 205 to 260 °C (400 to 500 °F). Figure 10 is a continuous-cooling time-temperature-transformation diagram for a typical high-chromium iron designed for use in moderately heavy sections.

Fig. 10 Continuous-cooling transformation diagram for a white cast iron. Composition: 2.96TC-0.93Si-0.79Mn-17.5Cr-0.98Cu-1.55Mo; austenitized at 955 °C (1750 °F) for 2.5 h. Ac₁ is the temperature at which austenite begins to form upon heating.

Microstructure. With rapid solidification, such as that which occurs in thin-wall castings or when the iron solidifies against a chill, the austenite dendrites and eutectic carbides are fine grained, which tends to increase fracture toughness. In low-chromium white irons, rapid solidification will also reduce any tendency toward formation of graphite. The presence of graphite severely degrades abrasion resistance. Chills in the mold can be used to promote directional solidification (Fig. 11) and therefore reduce shrinkage cavities in the casting. Certain inoculants, notably bismuth, may beneficially alter the solidification pattern by reducing spiking or by producing a finer as-cast grain size.

1000×

Immediately after solidification, the microstructure of unalloyed or low-chromium white irons consists of austenite dendrites, containing up to about 2% C, surrounded by M_3C carbides (Fig. 12). When the chromium content of the iron exceeds about 7 wt%, the structure contains M_7C_3 eutectic carbides surrounded by austenite (Fig. 13). This reversal of the continuous phase in the structure tends to increase the fracture toughness of white irons, but only those irons that have a hypoeutectic or eutectic carbon equivalent. All hypereutectic white irons are relatively brittle and are seldom used commercially.

After a white iron casting has solidified and begins to cool to room temperature, the carbide phase may decompose into graphite plus ferrite or austenite. This tendency to form graphite can be suppressed by rapid cooling or by the addition of carbide-stabilizing alloying elements--usually chromium, although inoculating with tellurium or bismuth is also very effective. Austenite in the solidified white iron structure normally undergoes several changes as it cools to ambient temperature. If it is cooled slowly enough, it tends to reject hypereutectoid carbon, either on existing eutectic carbide particles or as particles, platelets, or spines within the

austenite grains. This precipitation occurs principally between about 1040 and 760 °C (1900 and 1400 °F). The rate of precipitation depends on both time and temperature.

As the austenite cools further, through the range of 705 to 540 °C (1300 to 1000 °F), it tends to transform to pearlite. This transformation, however, can be suppressed by rapid cooling and/or by the use of pearlite-suppressing elements in the iron.

Nickel, manganese, and copper are the principal pearlite-suppressing elements. Chromium does not contribute significantly to pearlitic suppression (hardenability) in many white irons, because most of the chromium is tied up in carbides. Molybdenum, a potent carbide former, is also tied up in carbides; however, in high-chromium irons, there is enough chromium and molybdenum remaining in the matrix to contribute significantly to hardenability.

Upon cooling below about 540 °C (1000 °F), the austenite may transform to bainite or martensite, thus producing martensitic white iron, which is currently the most widely used type of abrasion-resistant white iron. Martensitic white irons usually contain some retained austenite, which is not considered objectionable unless it exceeds about 15%. Retained austenite is metastable and may transform to martensite when plastically deformed at the wearing surface of the casting.

Silicon has a substantial influence on the microstructure of any grade of white iron. Normally, silicon content exceeds 0.3%, and it may range as high as 2.2% in some of the high-chromium grades. During the solidification of unalloyed or low-alloy irons, silicon tends to promote the formation of graphite, an effect that can be suppressed by rapid solidification or by the addition of carbide-stabilizing elements. After solidification, either while the casting is cooling to ambient temperature or during subsequent heat treatment, silicon tends to promote the formation of pearlite in the structure if it is the only alloy present. However, in the presence of chromium and molybdenum, both of which suppress ferrite, silicon has a minimal effect on ferrite and substantially suppresses bainite. In certain alloy white irons with high retained-austenite contents, increasing the silicon content raises the M_s temperature of the austenite, which in turn promotes the transformation of austenite to martensite. Silicon is also used to enhance the hardening response when the castings are cooled below ambient temperature. The microstructure of heat-treated high-chromium, high-molybdenum white iron is shown in Fig. 14.

Fig. 14 Structure developed by the heat treatment of a high-chromium iron. Specimen from a chute liner 51 mm (2 in.) thick, containing 2.6% TC, 1.5% Si, 1.1% Mn, 14.3% Cr, and 3.0% Mo; reheated to 1040 to 1065 °C (1900 to 1950 °F) and air cooled. Mechanical Properties. Hardness is the principal mechanical property of white iron that is routinely determined and reported. Other (nonstandard) tests to determine strength, impact resistance, and fracture

toughness are sometimes employed by individual users, producers, or laboratories. Because of the difficulty of preparing test specimens, especially from heavy-section castings, these nonstandard tests are seldom used for routine quality control. Two exceptions are the tumbling-breakage test and the repeated-drop test, which have been routinely used by certain producers for testing grinding balls.

Minimum hardness values for pearlitic white irons are 321 HB for the low-carbon grade and 400 HB for the high-carbon grade. A chill cast high-carbon 2% Cr white iron may reach a hardness of about 550 HB. A typical hardness range for a sand cast high-carbon grade is about 430 to 500 HB.

Table 3 lists minimum specified hardness levels, together with maximum annealed hardness and typical maximum annealed hardness and typical maximum section thickness, for the martensitic compositions listed in Table 2. The minimum hardness specified for the hardened (heat-treated) class II castings is well below the average expected hardness. These irons, when fully hardened so that they are free from high-temperature products of austenite transformation, will have hardness values ranging from about 800 to 950 HV (depending on retained austenite content), as for example the 847 to 907 HV range in Fig. 10. The 800 to 950 HV range is equivalent to 700 to 790 HB or 62.5 to 67.5 HRC. For optimum abrasion resistance of the class I irons in Table 3, the minimum Brinell hardness, as measured with a tungsten carbide ball or converted from HV or HRC values, should be 700 HB.

diameter.

Hardness conversions for white irons are somewhat different from the published data for steel. Table 4 lists data for two classes of white irons: high-chromium irons and nickel-chromium irons. Because of inherent variations in structure for many cast irons, hardness conversion must be made cautiously. For example, Brinell hardness tests are more consistent and reliable for coarse structures such as those typical of heavy sections.

The tensile strength (in reality, the fracture strength) of pearlitic white irons normally ranges from about 205 MPa (30 ksi) for high-carbon grades to about 415 MPa (60 ksi) for low-carbon grades. The tensile strength of martensitic irons with M_3C carbides ranges from about 345 to 415 MPa (50 to 60 ksi), while high-chromium irons, with their M_7C_3 -type carbides, usually have tensile strengths of 415 to 550 MPa (60 to 80 ksi). Limited data indicate that the yield strengths of white irons are about 90% of their tensile strengths. These data are extremely sensitive to variations in specimen alignment during testing. Because of the near-zero ductility of white irons, the usefulness of tensile test data for design or quality assurance is very limited.

Transverse strength, which is an indirect measurement of tensile strength and tensile ductility, can be determined with a moderate degree of accuracy on unmachined cast test bars. The product of transverse strength and deflection provides one measure of toughness. Table 5 lists typical values of transverse strength, deflection, and toughness for as-cast test bars. These values should be considered very general; the wide spread of these data emphasizes that properties depend to a marked degree on composition and the conditions under which the castings were produced.

Table 5 Transverse strengths and relative toughness of various pearlitic and martensitic white irons in the as-cast condition

Typical mechanical properties of alloyed white irons are given in Fig. 15 (Ref 1). Hardness, yield strength in compression, and impact energy absorbed by unnotched Charpy specimens are shown for as-cast austenitic and heat-treated martensitic irons. The chromium-molybdenum iron conforms to ASTM class II type E (see Table 2), the high-chromium iron conforms to ASTM class III type A, and the Ni-Hard IV iron conforms to ASTM class I type D.

Fig. 15 Typical mechanical properties of white cast irons. Source: Ref 1

The elastic modulus of a white iron is considerably influenced by its carbide structure. An iron with M_3C eutectic carbides has a tensile modulus of 165 to 195 GPa (24 to 28×10^6 psi), irrespective of whether it is pearlitic or martensitic, while an iron with M_7C_3 eutectic carbides has a modulus of 205 to 220 GPa (30 to 32×10^6 psi).

Physical Properties. The density of white irons ranges from 7.50 to 7.75 g/cm³ (0.271 to 0.280 lb/in.³). Increasing carbon content tends to decrease density; increasing the amount of retained austenite in the structure tends to increase density. Other physical properties are summarized in Table 6 for low-carbon white iron and martensitic nickel-chromium white iron.

Table 6 Physical properties of selected alloy cast irons

Abrasion Resistance. The relative abrasion resistance of various types of white iron has been extensively studied in commercial service and in many types of laboratory abrasion tests. In general, martensitic white irons have substantially better abrasion resistance than pearlitic or austenitic white irons. There can be substantial differences in abrasion resistance among the various martensitic irons. The degree of superiority of one type over another can also vary considerably, depending on the application and also on whether abrasive wear is due to gouging, high-stress (grinding) abrasion, or low-stress scratching or erosion. In addition, performance in a wet environment may be quite different from that in a dry environment.

For nickel-chromium martensitic white irons, there are conflicting data as to the relative serviceability of sand cast and chill cast parts subjected to abrasive wear. This is not particularly surprising, because many of the data were obtained in test using abrasive ores where the nature of the gangue was incompletely defined or largely ignored. As discussed in the article "Wear Failures" in *Failure Analysis and Prevention*, Volume 11 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*, it is very important to completely characterize any abrasive substance, particularly ores and other earthy mixtures, so that the results of tests and service evaluations can be properly analyzed.

The hardness of the abrasive material has a marked influence on relative abrasion rates. For example, when the abrasive is silicon carbide, which is hard enough to scratch M_3C and M_7C_3 carbides as well as martensite and pearlite, there may be little difference in relative wear rates among any of the white irons. However, with silica (the abrasive most commonly encountered in service), which is not hard enough to scratch M_7C_3 carbides but may scratch M_3C carbides and definitely will scratch martensite and pearlite, high-chromium white irons, with their M_7C_3 carbides, tend to provide superior performance. If the abrasive mineral is a silicate of intermediate hardness such as feldspar, which (theoretically) will not scratch fully hard martensite but will scratch pearlite, any of the martensitic white irons should perform much better than any of the pearlitic white irons. An indication of relative abrasion resistance can be obtained by comparing the hardness of the commonly encountered abrasive minerals with the hardness of the microconstituents in white irons, as indicated in Table 7.

Table 7 Hardness of various abrasive minerals as related to hardness of microconstituents in white iron

	Mohs' scale	Constituent hardness	
		HRC	HV
Diamond	10	...	8000
Silicon carbide	2500
Tungsten carbide	2400
Corundum (Al_2O_3)	9	...	2000
M_7C_3 -type carbides in high-chromium irons	1500-1800
Topaz	8	...	1300
M_3C -type carbides in low-chromium irons	1060-1240
Quartz (silica)	7	...	800-1000
Garnet	7	...	800-1000
High-carbon martensite	$6\frac{1}{2}$	62	770-800
Feldspar	6	...	500-600
Austenite in high-chromium irons	...	35-40	350-400

The relatively low hardness of the retained austenite in high-chromium irons (Table 7) deserves special consideration. Because this austenite tends to work harden rapidly and may also transform to martensite, it is quite abrasion resistant when severely loaded. However, most abrasion tests and field experience indicate that irons containing considerable retained austenite are not as abrasion resistant as those put into service with fully martensitic microstructures.

The relative wear rates of several types of white iron, as determined in various laboratory tests, are listed in Table 8 (Ref 2). Field test data for grinding mill liners are also given in Table 8. For comparison, the abrasion resistance of a fully hardened, high-carbon martensitic steel is included, when available.

Table 8 Abrasion resistance and wear rates of selected white irons

Material designation	ASTM designation		Abrasion resistance			Relative wear rate in grinding mill liners ^(a)
			Gouging wear ratio	Weight loss, g		
	Class	Type			Pin test	
Ni-Cr-HC	I	A	0.035	105-109
Ni-Cr-LC	I	B	0.151	...	0.055	...
15% Cr-Mo-LC	II	B	0.076	...	0.065	88-90
15% Cr-Mo-HC	II	C	0.044	...	0.036	...
20% Cr-Mo-HC	II	E	0.081	0.042	0.054	...
25% Cr	III	A	0.127	...	0.099	98-100
Martensitic steel (1C-5Cr-1Mo)	0.077	...	100

(a) Martensitic steel used as a reference and assigned a value of 100. Values <100 indicate a more wear-resistant material; >100 indicates a less wear-resistant material.

The laboratory tests include:

- A jaw crusher test, which provides a *gouging wear ratio* between the weight losses of the test material and a hardened and tempered structural steel plate (lower ratios indicate greater resistance to abrasion)
- Weight-loss data for a *pin test*, in which a test pin is continually abraded by fresh garnet abrasive cloth

for a designated distance

- Weight-loss data for a *rubber-wheel test*, in which the specimen is abraded by a sand slurry forced between the specimen and a rotating rubber wheel under a designated load

The gouging wear test simulates rock-crushing service; the pin test provides high-stress abrasion, as found in various types of grinding mills; and the rubber-wheel test simulates low-stress abrasion, as found in classifiers and other equipment handling abrasive slurries.

The relative wear rates in grinding mill liners were obtained from field tests in which liner segments of various materials were weighed before and after service (Ref 3). The martensitic steel weight loss was assigned a value of 100, rates less than 100 indicate a more wear-resistant material, and rates greater than 100 indicate a material less resistant to wear.

Components of mills for grinding cement clinker have been made from several different irons and steels. The relative wear rates of mills in this service as determined during a field test are shown in Fig. 16.

Fig. 16 Service performance in grinding cement clinker

Alloy Cast Irons

Revised by Richard B. Gundlach, Climax Research Services; and Douglas V. Doane, Consulting Metallurgist

Corrosion-Resistant Cast Irons

The corrosion resistance of gray cast iron is enhanced by the addition of appreciable amounts of nickel, chromium, and copper, singly or in combination, or silicon in excess of about 3%. Chemical composition ranges bracketing some of the more widely used corrosion-resistant cast irons are given in Table 1. Typical mechanical property ranges for the four basic types of corrosion-resistant cast iron are given in Table 9; physical property ranges for these irons are given in Table 6.

Table 9 Typical mechanical properties of corrosion-resistant cast irons

Up to 3% Si is normally present in all cast irons; in larger percentages, silicon is considered an alloying element. It promotes the formation of a strongly protective surface film under oxidizing conditions such as exposure to oxidizing acids. Relatively small amounts of molybdenum and/or chromium can be added in combination with high silicon. The addition of nickel to gray iron improves resistance to reducing acids and provides high resistance to caustic alkalies. Chromium assists in forming a protective oxide that resists oxidizing acids, although it is of little benefit under reducing conditions. Copper has a smaller beneficial effect on resistance to sulfuric acid.

High-silicon irons are the most universally corrosion-resistant alloys available at moderate cost. They are widely used for handling the corrosive media common in chemical plants, even when abrasive conditions are also encountered. When the silicon content is 14.2% or higher, these irons exhibit a very high resistance to boiling sulfuric acid (Fig. 17a). They are especially useful when the concentration of sulfuric acid is above 50%, at which point they are virtually immune to attack. As shown in Fig. 17(b), the high-silicon irons are also very resistant to nitric acid. Increasing the silicon content to 16.5% makes the alloy quite resistant to corrosion in boiling nitric and sulfuric acids at nearly all concentrations, but because this is accompanied by a reduction of mechanical strength, it is not ordinarily done in the United States.

Fig. 17 Useful life of plain and alloyed cast irons in acid alkaline media as a function of temperature and concentration of the corrodents. (a) Sulfuric acid. (b) Nitric acid. (c) Hydrochloric acid. (d) Sodium hydroxide

The 14.5% Si iron is less resistant to the corrosive action of hydrochloric acid, but this resistance can be improved by additions of chromium and molybdenum and can be further enhanced by increasing the silicon

content to 17%. The chromium-bearing silicon irons are very useful in contact with solutions containing copper salts, free wet chlorine, or other strongly oxidizing contaminants.

The high-silicon irons are very resistant to organic acid solutions at any concentration or temperature. However, their resistance to strong hot caustics is not satisfactory for most purposes. They are resistant to caustic solutions at lower temperatures and concentrations, and (although they are no better than unalloyed gray iron in this regard) they can be used where caustics and other corrosives are mixed or alternately handled. They have no useful resistance to hydrofluoric or sulfurous acids.

High-silicon irons have poor mechanical properties and particularly low thermal and mechanical shock resistance. These alloys are typically very hard and brittle, with a tensile strength of about 110 MPa (16 ksi) and a hardness of 480 to 520 HB. They are difficult to cast and are virtually unmachinable. Their considerable use stems from their outstanding resistance to acids such as those mentioned above. They are widely used for drain pipe in chemical plants, laboratories, hospitals, and schools. High-silicon iron towers, tubes, and fittings are standard equipment for concentrating sulfuric and nitric acids in the explosives and fertilizer industries.

High-silicon iron pumps, valves, mixing nozzles, tank outlets, and steam jets are widely used for handling severe corrodents such as chromic acid, sulfuric-acid slurries, bleach solutions, and acid-chloride slurries, which are frequently encountered in plants that manufacture paper, pigments, or dye stuffs or that use electroplating solutions. High-silicon irons are also widely used for anodes in impressed-current cathodic-protection systems, especially where aggressive environments such as seawater or chloride soils are encountered.

The mechanical strength and shock resistance of high-silicon irons can be improved by lowering the silicon content to 12% or slightly less; this practice is occasionally followed in the United States and Europe. However, reducing the silicon 12% causes a significant reduction in corrosion resistance and therefore is feasible only in applications where the loss in corrosion resistance has a minimal effect on service life or is offset by the benefit derived from the increase in strength.

High-chromium irons containing 20 to 35% Cr give good service with oxidizing acids, particularly nitric, but are not resistant to reducing acids. These irons are also reliable for use in weak acids under oxidizing conditions, in numerous salt solutions, in organic acid solutions, and in marine or industrial atmospheres.

The corrosion resistance of high-chromium cast iron to nitric acid is exceptional; it resists all concentrations of this acid up to 95% at room temperature. Its corrosion rate is less than 0.13 mm (0.005 in.) per year at all temperatures up to the boiling point for concentrations up to 70%. In handling nitric acid, the chromium irons are complementary to high-silicon irons. The former exhibit excellent corrosion resistance to all concentrations and temperatures, except for boiling concentrated acids, while the latter give better results in stronger acid. Data relating corrosion resistance to temperatures and acid concentrations are shown in Fig. 17(b) for both high-chromium and high-silicon irons.

The low-carbon, high-chromium irons are satisfactory for annealing pots; lead, zinc, or aluminum melting pots; conveyor links; and other parts exposed to corrosion at high temperature. Because the corrosion resistance is imparted by chromium present in solid solution in the ferritic matrix, this element must be present in sufficient quantity to combine with carbon as chromium carbide and still remain in the desired amount in the ferrite. Chromium contents of 30 to 33% are common in irons for use under conditions of severe acid corrosion.

High-chromium irons are resistant to all concentrations of sulfurous acid at temperatures up to 80 °C (175 °F), to sulfite liquors used in the papermaking industry, to hypochlorite bleaching liquors at room temperature, to cold aluminum sulfate in concentrations up to 5%, and to some salts that hydrolyze to give acid solutions. They resist all concentrations of phosphoric acid up to 60% at temperatures up to the boiling point and 85% concentrations up to 80 °C (175 °F). They also have good resistance to aerated seawater and most mine waters, including acidic types.

Chromium cast irons have better mechanical properties than high-silicon irons and respond readily to heat treatment when chromium and carbon contents are suitably balanced. Tensile strength as high as 480 MPa (70 ksi) is obtained with a hardness of 290 to 340 HB. These alloys are generally resistant to shock and can be machined; both of these properties are improved when carbon content is lowered to about 1.2%. As carbon is increased, machinability in the annealed condition decreases; consequently, irons with carbon contents of 3% or more should be used only when no machining is required. The maximum service temperature for high-chromium irons is generally 815 to 1095 °C (1500 to 2000 °F).

High-Nickel Irons. High-nickel austenitic cast irons produced in several compositions, depending on desired properties and end use. Austenitic gray irons containing large percentages of nickel and copper are fairly resistant to mildly oxidizing acids, including dilute to concentrated sulfuric acid at room temperature. Their resistance to sulfuric acid is compared with that of other cast irons in Fig. 17(a). They are also fairly resistant to hydrochloric and some phosphoric acids at slightly elevated temperatures. Their useful range in hydrochloric acids is indicated in Fig. 17(c).

The corrosion behavior of high-nickel irons is similar to that of unalloyed gray iron in the presence of nitric acid. Although the nickel-containing iron exhibits better corrosion resistance than an 18-8 stainless steel, high-silicon irons are much better for both sulfuric and hydrochloric acids under the conditions shown in Fig. 17(a) and 17(c).

High-nickel irons exhibit fair resistance to some organic acids (such as acetic, oleic, and stearic acids) and to red oils. Irons with nickel contents of 18% or more are nearly immune to the effects of weak or strong alkalies and caustics, although subject to stress corrosion in strong hot caustics at stresses over 70 MPa (10 ksi). The resistance of these irons to various concentrations of sodium hydroxide at temperatures up to 260 °C (500 °F) is indicated in Fig. 17(d).

High-nickel irons are the toughest of all cast irons containing flake graphite. Although their tensile strength is relatively low, ranging from 140 to 275 MPa (20 to 40 ksi), they have satisfactory toughness and excellent machinability. High-nickel ductile irons, which are specially treated so that the graphite forms as spheroids rather than as flakes, have essentially the same corrosion resistance as high-nickel gray irons, but have much higher strength and ductility. A similar treatment applied to high-silicon iron provides no improvement in mechanical properties.

High-nickel irons provide satisfactory corrosion resistance at elevated temperatures up to about 705 to 815 °C (1300 to 1500 °F). Above this range, high-chromium irons are preferred.

Alloy Cast Irons

Revised by Richard B. Gundlach, Climax Research Services; and Douglas V. Doane, Consulting Metallurgist

Heat-Resistant Cast Irons

Heat-resistant cast irons are basically alloys of iron, carbon, and silicon having high-temperature properties markedly improved by the addition of certain alloying elements, singly or in combination, principally chromium, nickel, molybdenum, aluminum, and silicon in excess of 3%. Silicon and chromium increase resistance to heavy scaling by forming a light surface oxide that is impervious to oxidizing atmospheres. Both elements reduce the toughness and thermal shock resistance of the metal. Although nickel does not appreciably affect oxidation resistance, it increases strength and toughness at elevated temperatures by promoting an austenitic structure that is significantly stronger than ferritic structures above 540 °C (1000 °F). Molybdenum increases high-temperature strength in both ferritic and austenitic iron alloys. Aluminum additions are very potent in raising the equilibrium temperature (A_1) and in reducing both growth and scaling, but they adversely affect mechanical properties at room temperature.

The chemical composition ranges of some of the more widely used heat-resistant irons (both gray and ductile types) suitable for elevated-temperature service are given in Table 1. Typical physical properties are summarized in Table 6, and typical mechanical property ranges are given in Table 10. The performance of alloy gray irons at elevated temperatures is determined by a number of related properties, such as resistance to growth and oxidation, resistance to thermal shock, response to cyclic heating, creep resistance, rupture strength, and high-temperature fatigue strength.

Table 10 Typical mechanical properties of heat-resistant alloy cast irons

Type of iron ^(a)	Hardness, HB	Tensile strength		Compressive strength		Impact energy		Transverse breaking load ^(b)		Transverse deflection ^(b)	
		MPa	ksi	MPa	ksi	J	ft · lbf	kg	lb	mm	in.

Growth is the permanent increase volume that occurs in some cast irons after prolonged exposure to elevated temperature or after repeated cyclic heating and cooling. It is produced by the expansion that accompanies graphitization, expansion, and contraction at the transformation temperature, combined with internal oxidation of the iron. Gases can penetrate the surface of hot cast iron at the graphite flakes and oxidize the graphite as well as the iron and silicon. The occurrence of fine cracks, of crazing, may accompany repeated heating and cooling through the transformation temperature ranges because of thermal and transformational stresses.

Silicon contents of less than about 3.5% increase the rate of growth by promoting graphitization, but silicon contents of 4% or more retard growth. Both manganese and phosphorus decrease growth by acting as carbide stabilizers.

The carbide-stabilizing alloying elements, particularly chromium, effectively reduce growth in gray irons at 455 °C (850 °F) or above. Growth is not a problem below 400 °C (750 °F), except in the presence of superheated steam, where it can occur in coarse-grain irons at about 315 °C (600 °F). Even small amounts of chromium, molybdenum, and vanadium produce marked reductions in growth at the higher temperatures. The influence of chromium in reducing growth in gray iron at 800 °C (1470 °F) is shown in Fig. 18. These data indicate that in cyclic heating, including a total of 500 h at the upper temperature, a chromium content of about 2% serves to eliminate growth.

Fig. 18 Effect of chromium on the growth of cyclically heated gray iron. Growth is plotted as a function of the number of heating cycles and time at 800 °C (1470 °F).

Chromium irons containing 24 to 34% Cr show no appreciable growth at 1095 °C (2000 °F). In general, cast irons containing 20 to 35% Cr can be used regularly at about 980 °C (1800 °F) and for short periods up to 1095 °C (2000 °F) with satisfactory resistance to growth and scaling.

High-nickel gray and ductile irons are also quite resistant to elevated-temperature growth. For example, the growth of gray and ductile versions of high-nickel cast iron is compared to that of unalloyed gray iron in Table 11; these data are for continuous exposure to superheated steam at 480 °C (900 °F). In addition to resistance to growth, the austenitic gray and ductile irons are resistant to warpage and cracking in cyclic elevated-temperature service. This resistance is attributed to the absence of phase transformation, to moderate elastic moduli, and to good mechanical properties at about 595 to 760 °C (1100 to 1400 °F).

Table 11 Growth of high-nickel irons in superheated steam at 480 °C (900 °F)

Type of Iron	Growth, mm/m or 0.001 in./in., after		
	500 h	1000 h	2500 h
Gray iron (unalloyed)	2.3	5.2	14
High-nickel gray iron (20% Ni)	0.5	1.0	1.5
High-nickel gray iron (30% Ni)	0.3	0.45	0.48
High-nickel ductile iron (20% Ni)	0.3	0.5	0.5

Scaling. In addition to the internal oxidation that contributes to growth, a surface scale forms on unalloyed gray iron after exposure at sufficiently high temperature. The scale formed in air consists of a mixture of iron oxides. The important factor in scale formation is whether the scale, first, is essentially adherent and protective to the base metal or, second, tends to flake and permit continued oxidation of the metal.

Silicon, chromium, and aluminum increase the scaling resistance of cast iron by forming a light surface oxide that is impervious to oxidizing atmospheres. Unfortunately, these elements tend to reduce toughness and thermal shock resistance. The presence of nickel improves the scale resistance of most alloys containing chromium and, more important, increases their toughness and strength at elevated temperatures.

Carbon has a somewhat damaging effect above 705 °C (1300 °F) as a result of the mechanism of decarburization and the evolution of carbon monoxide and carbon dioxide. When these gases are evolved at the metal surface, the formation of protective oxide layers is hindered, and cracks and blisters may develop in the scale. Typical oxide penetration rates for unalloyed and alloyed cast irons and certain stainless steels in air, in a slightly reducing furnace atmosphere, and in sulfur-bearing flue gas are given in Tables 12, 13, and 14.

Figure 19 indicates the temperatures at which various silicon-chromium irons can be used with only slight or insignificant scaling in sulfur-free oxidation atmospheres. Greater scaling rates can be tolerated in some applications, so that higher useful temperatures are possible. The presence of large amounts of nickel, as in Nicrosilal, or aluminum would increase the temperature limits shown for the various silicon-chromium irons. For example, a 7% Al iron has adequate scale resistance to about 900 °C (1650 °F), while 16 to 25% Al irons are virtually scale free at 1095 °C (2000 °F).

Fig. 19 Relation of silicon and chromium contents to the scaling resistance of silicon-chromium irons. Indicated are the temperatures at which various irons can be used with very little or insignificant scaling in sulfur-free oxidizing atmospheres.

High-Temperature Strength. Measurements of short-time tensile strength, creep strength, and rupture strength provide a basis for evaluating the performance of metals at elevated temperatures. Creep rate increases with temperature and becomes an important design factor at elevated temperatures.

Creep is ordinarily reported in terms of strain for a specified period of time at a given tensile stress and temperature. Because cast irons can grow at elevated temperatures without the application of external stress, the measured increase in length is the sum of growth resulting from metallurgical causes and the mechanical elongation of creep.

Creep in gray iron is appreciably influenced by microstructure and composition. An unalloyed gray iron with a carbon equivalent of about 4% can usually be subjected to a tensile stress of 70 MPa (10 ksi) at 400 °C (750 °F) without exceeding a creep rate of 1% in 10,000 h. Low-alloy irons exhibit even less creep under similar conditions. Ductile irons may sustain stresses up to 185 MPa (27 ksi) at 425 °C (800 °F) without exceeding a creep rate of 1% in 10,000 h. Some austenitic ductile irons have about the same creep strength at 540 °C (1000 °F) as the unalloyed ductile irons display at 425 °C (800 °F).

The short-time high-temperature strength of a metal is taken as the stress that is sufficient to break a standard tension test specimen in a short period of time at elevated temperature. Often, the correlation between the high-temperature strength and load-carrying capacity of a metal over long periods of time is poor or nonexistent. Short-time tensile data for several alloy irons are reported in Fig. 20.

(a)

(b)

Fig. 20 Short-time elevated-temperature tensile strength of several (a) alloy irons and (b) ferritic nodular irons

Because of the inadequacy of the short-time tension test, creep rupture test data are used more frequently in the evaluation of high-temperature properties. Although creep tests are performed at stresses that will not break the specimen, rupture tests are run to failure. Typical stress rupture data for the austenitic 20Ni, 20Ni-1Mo, 30Ni, and 30Ni-1Mo ductile irons are given in Fig. 21, along with data for ferritic 4Si and 4Si-1Mo. For comparison, stress rupture data for a cast 19Cr-9Ni stainless steel (ASTM A 297, grade HF) are included.

Fig. 21 Typical stress-rupture properties of high-nickel heat-resistant ductile irons. (a) At 595 °C (1100 °F). (b) At 705 °C (1300 °F). Source: Ref 6

High-Silicon Irons. Although intermediate amounts of silicon increase the rate of growth in cast iron by increasing the rate of graphitization, additions of 4.5 to 8% Si greatly reduce both scaling and growth. Silicon also has the advantage of raising the transformation temperature to about 900 °C (1650 °F), thus increasing the operating temperature range that may be employed without encountering a phase change (Ref 6).

Ferritic high-silicon gray iron is rather brittle and has a low resistance to thermal shock at room temperature. However, it is superior to ordinary gray iron above about 260 °C (500 °F). An austenitic gray iron containing 5% Si, 18% Ni, and 2 to 5% Cr exhibits considerably better toughness and thermal shock resistance. Both the plain silicon and the Ni-Cr-Si irons are British developments, the former known commercially as Silal and the latter as Nicrosilal. They exhibit excellent resistance to scaling in air up to 815 °C (1500 °F), and the Ni-Cr-Si iron can be successfully employed in sulfurous atmospheres. The maximum temperature for use of these irons is reported to be 900 °C (1650 °F) for the plain silicon iron and 955 °C (1750 °F) for the Ni-Cr-Si iron. Silicon-containing compositions are also available in ferritic ductile iron.

High-Chromium Irons. Chromium is widely used in heat-resistant irons because of its stabilizing influence on carbides, which deters growth, and its tendency to form a tight, protective oxide. Substantial improvement in oxidation resistance is obtained by the addition of 0.5 to 1% Cr for many applications up to 760 °C (1400 °F). Further improvement in resistance to scaling and growth at 760 °C (1400 °F) without excessive loss in toughness and machinability is reported for irons with up to 2% Cr.

The effect of chromium additions on cyclic heating characteristics and resistance to scaling is discussed in the section "Growth" in this article. Pertinent data are given in Fig. 18 and 19. Machinable castings with considerable heat resistance can be obtained with rather small additions of both chromium and nickel to cast iron. Chromium additions of 15 to 35% are employed for excellent oxidation and growth resistance at about 980 °C (1800 °F) and even up to 1095 °C (2000 °F) in oxidizing atmospheres or in the presence of certain chemicals.

The high-chromium irons exhibit a characteristically white structure and can be produced with fair machinability and good strength. Low silicon and carbon contents are desirable when toughness and thermal shock resistance are required. The thermal shock resistance of these irons is good, but their toughness is quite limited, even when carbon and silicon contents are low.

High-Nickel Irons. The austenitic cast irons containing 18 to 36% Ni, up to 7% Cu, and 1.75 to 4% Cr are used for both heat-resistant and corrosion-resistant applications. Known as Ni-Resist, this type of iron exhibits good resistance to high-temperature scaling and growth up to 815 °C (1500 °F) in most oxidizing atmospheres, good performance in steam service up to 530 °C (990 °F), and can handle sour gases and liquids up to 400 °C (750 °F). The maximum temperature of use is 540 °C (1000 °F) if appreciable sulfur is present in the atmosphere. Austenitic cast iron can be employed at temperatures as high as 950 °C (1740 °F). Austenitic irons have the advantage of considerably greater toughness and thermal shock resistance than the other heat-resistant alloy irons, although their strength is rather low.

High-nickel ductile irons are considerably stronger and tougher than the comparable gray irons. Tensile strengths of 400 to 470 MPa (58 to 68 ksi), yield strengths of 205 to 275 MPa (30 to 40 ksi), and elongations of 10 to 40% can be realized in high-nickel ductile irons.

High-Aluminum Irons. Alloy cast irons containing 6 to 7% Al, 18 to 25% Al, or 12 to 25% Cr plus 4 to 16% Al are reported to have considerably better resistance to scaling than several other alloy irons, including the high-silicon type. These irons have been little used commercially because of brittleness and poor castability.

Alloy Ductile Irons. Various corrosion-resistant and heat-resistant alloy irons can also be cast as ductile iron, with the graphite in the form of spheroids rather than in the normal flake-graphite shape characteristic of gray iron. When the graphite is present as spheroids, the metal exhibits improved elastic behavior, higher modulus of elasticity, a definite yield point, higher tensile strength, and improved ductility and toughness. Where service

applications require these improved properties, alloy ductile irons can be efficiently utilized, although their metallurgical and production characteristics are more complex than those of comparable gray irons.

Alloy Cast Irons for Automotive Service. The most important automotive application of alloy cast irons is in brake drums and disks, for which the material is required to have a combination of high heat capacity, good thermal conductivity, and high emissivity so that it can dissipate a large amount of heat per unit volume. Also, to maintain strength and dimensional stability during cyclic heating and cooling, the material must have adequate high-temperature strength and resistance to thermal shock and must resist growth due to changes in structure.

Low-silicon chromium-molybdenum gray cast iron is generally preferred for automotive disk or drum brakes. Composition and graphite content are closely controlled to maintain adequate high-temperature strength, along with the graphite size and distribution that give adequate thermal conductivity and machinability. In general, decreasing silicon content from 2.5 to 1.5% increases thermal conductivity by about 10%. At the same time, the carbon equivalent must be kept relatively high to ensure solidification as gray iron rather than as white iron. Although most alloying elements decrease the thermal conductivity of gray iron, their effect is not as great as that of silicon. Gray irons alloyed with chromium and molybdenum are reported to have better thermal conductivity than unalloyed gray irons of comparable silicon and carbon contents. The alloy gray irons also have more stable structures and better stress rupture properties than the unalloyed irons.

Steel Processing Technology

R.I.L. Guthrie and J.J. Jonas, McGill Metals Processing Center, McGill University

Liquid Processing of Steel

The physical chemistry of steelmaking may appear deceptively simple for integrated steel mill operations where ore from the ground is converted into steel. The central reaction merely involves the reduction of iron oxide by carbon:

The final reduction of oxide to liquid iron requires high temperatures of the order of 1600 °C (2910 °F), to overcome the chemical barrier to oxide reductions and the physical, or thermal, barrier of fusing iron. However, to yield a final steel product with the correct chemistry, quality, and property characteristics, the series of processes depicted in Fig. 1 is typically required.

Fig. 1 Major steps in processing liquid iron into high-quality steels. RH, Ruhrstahl Hereaus process

Ironmaking

The first step in processing liquid iron into high-quality steel involves an ironmaking blast furnace, which has evolved over the centuries to become an efficient countercurrent exchanger of heat and of mass, or oxygen (Fig. 2). Iron oxide (in pellet or sinter form), coke, and limestone are successively charged through the top of the furnace. The charge slowly descends through the shaft (an 8-h journey) and is gradually heated by hot ascending gases (CO , CO_2 , N_2 , H_2 , H_2O) with a transit time of about 3 s. Because the gas that is lower in the furnace is richer in carbon monoxide, it has a more reducing effect on iron oxides. Thus, the pellets are gradually reduced as a result of mass transfer of carbon monoxide (and hydrogen) from the gas phase into the pellet:

Fig. 2 Principal zones and component parts of an iron blast furnace. Source: Ref 1

Final deoxidation is accomplished down in the cohesive zone (Fig. 2), where high temperatures and highly reducing conditions result in the reduction of wustite (FeO) to iron. Impurities such as silica, sulfur, alumina, and magnesia, which are present in the original pellets and coke, associate with the lime/dolomite and are removed as a molten slag. To ensure that this slag is fluid, a composition of about 40% SiO_2 , 50% CaO (+ MgO) and 10% Al_2O_3 is desired, thereby placing it within the temperature valley, or well, of a ternary eutectic region. The final reduction of the charged pellets, ore, or sinter takes place either by:

or

The reaction in Eq 4 is termed indirect reduction because the iron oxide is reduced through the intervention of a gaseous reductant. The reaction in Eq 5 is termed direct reduction because the direct contact of wustite with coke leads to droplets of iron that fall through the dripping zone into the hearth.

The CO_2 of Eq 4 reacts immediately with the carbon of the hot coke to form more CO as follows:

This CO_2/CO reaction is often termed the solution loss reaction because it involves the dissolution of coke by CO_2 .

Although the obvious purpose of a coke layer is to act as a reductant, the descending coke also plays another critical role. Part of the coke (known as the dead man) forms a supporting pillar for the overlaying burden (the ratio of iron and flux to coke and other fuels in the charge). In the region below the cohesive, or sticky, zone (Fig. 2), the remainder of the charge either is molten or is melting (that is, it is composed of slag and pig iron). The final role of the coke is to burn with hot air entering the coke raceways through the tuyeres, thereby generating the high-temperature heat needed for smelting.

Cokemaking. The production of coke required for the tasks described above is also a formidable, capital-intensive operation. The process involves the destructive distillation of metallurgical-grade coals in the coking chambers of the by-product coke ovens. The heat that is needed to distill the volatiles is transferred through the brickwork from adjacent vertical flues by combustion of enriched blast furnace off-gases. After an induction time of approximately 17 h, the incandescent coke is pushed out of the slot ovens into transfer railway cars. During its fall the column of coke breaks apart, forming large lumps that are then transferred to the quenching tower, where an intense and normally intermittent water spray quenches them for subsequent charging into the blast furnace. Retained moisture is kept to a minimum because of the endothermic character of the moisture and consequent thermal load in the blast furnace.

Blast Furnace Stove Use. To achieve overall thermal efficiency, and to generate the high temperatures required for the reduction to iron in the hearth region of the blast furnace, the incoming blast air is preheated to about 1000 °C (1830 °F) prior to its entry through the water-cooled copper tuyeres. This is accomplished by passing the cold-air blast through a stacked vertical column of preheated (hot) bricks in one of three blast furnace stoves. Because the cold air gradually extracts the stored heat, a separate heating phase is also necessary. This is effected by shutting off the cold-air blast to the stove, opening up the gas valve, and burning enriched blast furnace off-gas (cleaned with water scrubbers, and electrostatic precipitators) to bring the cooled checkerwork of bricks back up to temperature. Because higher preheat temperatures translate directly into lower coke rates per net tonne of hot metal (NTHM), this heating and cooling cycle requires careful optimization.

Current Blast Furnace Technology. Over the years, significant improvements in burden preparation (such as the development of uniformly sized pellets) and burden layering techniques have enhanced the kinetic efficiency of gas/solid and heat/mass transfer interactions. Higher air blast preheat temperatures and improved coke properties have also helped to reduce coke requirements from about 910 kg (2000 lb) per NTHM in the 1950s to current levels of 455 kg (1000 lb) per NTHM.

The iron that is tapped from the blast furnace is saturated with about 4.4% (or 22 at.%) C. It also contains other impurities that have been reduced from the oxides contained within the iron ore charge. Consequently, the hot metal also contains about 0.3 to 1.3 wt% $(\text{Si})_{\text{Fe}}$, 0.5 to 2 wt% $(\text{Mn})_{\text{Fe}}$, 0.1 to 1.0 wt% $(\text{P})_{\text{Fe}}$ and 0.02 to 0.08 wt% $(\text{S})_{\text{Fe}}$. The dissolved sulfur is largely derived from sulfur contained in the coking coal. Dissolved nitrogen levels of the order of 100 ppm would be typical from the air blast. To meet the stringent requirements for high-quality steels, these impurities $[(\text{C}, \text{S}, \text{N}, \text{P} \dots)_{\text{Fe}}]$ must be brought to very low residual levels using the sequence of operations described below.

Hot Metal Desulfurization

Hot metal from the blast furnace is usually treated with lime, calcium carbide, magnesium, or mixtures of these substances to remove sulfur from the iron. The reactions taking place can be written as:

Enhanced desulfurization can be carried out in a blast furnace by using increased slag volumes to absorb the sulfur, but this method requires higher coke rates. Therefore, such practices were abandoned in the 1960s in favor of desulfurization external to the blast furnace.

It is important to remember that calcium and magnesium oxides are much more stable than their sulfide counterparts, calcium sulfide and magnesium sulfide. Consequently, these desulfurizing operations are only effective if dissolved oxygen levels within the iron are low. The presence of iron saturated with carbon ensures this condition; the fundamental interrelation between dissolved carbon and dissolved oxygen in high-carbon molten iron is (Ref 2):

$$k_{1600^\circ\text{C}}^{\text{eq}} = \frac{P_{\text{CO}}(\text{atm})}{\text{wt}\% \text{C} \text{ wt}\% \text{O}} ; 660 \quad (\text{Eq 11})$$

where K^{eq} is the thermodynamic equilibrium constant for Eq 10.

The insertion of $\text{wt}\%(\text{C})_{\text{Fe}} = 4.4 \text{ wt}\%$ for hot metal would show $\text{wt}\%(\text{O})_{\text{Fe}} \sim 3 \text{ ppm}$ for P_{CO} at atmospheric pressure if equilibrium applies. It is for this reason that desulfurization is so effective in hot metal. Calcia-rich slags have very high sulfur partition ratios with iron (~ 400). By contrast, sulfur partitioning in the steelmaking step is at best about 4 to 1 between a basic oxygen furnace (BOF) slag and oxygen-rich steel. Consequently, as much as possible of the sulfur-rich product that floats on the hot metal needs to be scraped or slagged off to prevent the sulfur from reverting to the metal during subsequent (low-carbon) steelmaking steps.

Current Hot-Metal Desulfurization Technology. The well-advanced process technology for desulfurization generally involves the submerged pneumatic injection of, for example, calcium carbide powder that is carried by nitrogen through a deeply submerged refractory-coated steel pipe of about a 25 mm (1-in.) inside diameter into hot metal contained within the torpedo car. This vessel (Fig. 1) is customarily used to transport hot metal from the ironmaking facilities to steelmaking operations downstream. Typical industrial practices reduce residual sulfur levels down to 0.01% to 0.02% $(\text{S})_{\text{Fe}}$. The desulfurized hot metal usually is transported in the torpedo car from the blast furnace to the steelmaking shop, where it is emptied into the transfer ladle. As mentioned, any slag carryover into the hot metal transfer ladle needs to be removed prior to charging hot metal into the BOF in order to prevent sulfur reversion.

Japanese manufacturers can produce steels with residual hot metal levels of 1 to 2% P; they achieve dephosphorization ahead of the steelmaking step by using injections of sodium carbonate. Because strong compound-forming tendencies exist between phosphorus and sodium, as they do for sulfur and sodium, simultaneous desulfurization and dephosphorization is possible, provided the hot metal has first been desiliconized.

Steelmaking

First-Stage Refining. Because the blast furnace has produced hot metal saturated with carbon and containing other elements, the next operation requires that these impurities (particularly phosphorus) be removed to the required degree. Integrated steel plants normally rely on pneumatically blown oxygen vessels to accomplish these reactions. In a typical BOF, high-velocity (supersonic) jets of pure oxygen are blown onto the hot metal (Fig. 3). Dissolved carbon is oxidized and escapes as carbon monoxide (primarily) and carbon dioxide from the mouth of the vessel, while the other oxidized impurities (Si, Mn, P)_{Fe} enter the slag by fluxing with additions of burnt lime (CaO).

Fig. 3 Principal zones and component parts of a basic oxygen furnace for the production of steel in a melt shop. (a) Typical plant layout. (b) BOF vessel

To compensate for the vast amounts of heat liberated during these oxidation reactions, about 30% of the total charge to the furnace comprises steel scrap as coolant. The scrap coolant is required to prevent the temperature of the molten steel from exceeding 1650 °C (3000 °F) and thereby causing unnecessary refractory erosion. Once again, highly complex heat, mass, and fluid transport mechanisms are involved. For example, mass transfer of bath carbon to the scrap metal surfaces effectively dissolves light-section scrap, even though bath temperatures are well below the melting point of the scrap (1500 °C, or 2730 °F) during the major portion of a blow (Fig. 4). Once the bath temperature exceeds the scrap melting range (1500 to 1540 °C, or 2730 to 2800 °F), normal thermal processes that involve turbulent heat transfer will melt the scrap, which finally becomes assimilated into the molten bath. The removal of dissolved carbon as gas and the removal of dissolved silicon, manganese, and phosphorus to an upper slag phase takes place sequentially (Fig. 4), according to:

Fig. 4 Removal of elements from the bath in a BOF process. Source: Ref 3

It should be emphasized that the exact transfer mechanisms are obscure and tend to remain so, due both to the opacity of the system and to the experimental difficulties and restrictions involved in direct measurements of important process variables at 1600 °C (2910 °F). However, the fact that the carbon drops linearly with time during the blow (following silicon elimination) indicates that the rate of oxygen supply controls the rate of decarburization; this is evident except at very low carbon levels, where the curve in Fig. 4 tails off with time.

Thus, towards the end of a BOF blow, the transport of dissolved carbon up to the fire point, where the oxygen jets impinge on the metal bath, has difficulty keeping up with the supply of oxygen. As a result, oxygen begins to dissolve in the steel bath at an increasing rate as the carbon-oxygen reaction heads away from the equilibrium curve for $(C)_{Fe}$ and $(O)_{Fe}$ in contact with a carbon monoxide environment at a partial pressure of 0.1 MPa (1 atm). Figure 5 illustrates the trajectory of the carbon-oxygen evolution as a function of process. The BOF-related curves start moving sharply higher as carbon levels drop below about 0.07 wt% C. The rapid increases in dissolved oxygen imply dirtier steels because greater amounts of deoxidizers (Al, Fe-Si) are needed to remove this oxygen, which is in the form of condensed oxide inclusions.

Fig. 5 Equilibrium curve for dissolved carbon and oxygen compared with operational carbon-oxygen trajectories for various steelmaking processes. The isopercentage error lines illustrate the relative importance of carbon to oxygen diffusion on carbon-oxygen kinetics. Q-BOP, quick-quiet basic oxygen process; LBE, lance bubbling equilibrium; KMS, Kloeckner Metallurgy Scrap; BOF, basic oxygen furnace. Source: Ref 1

Second-Stage Refining and Technology Advances. The recognition that the stirring being provided by the top-blown jet of a BOF furnace toward the end of the refining process was inadequate, together with the development of the Savarde-Lee shrouded tuyere (Ref 4), triggered a remarkable change in the technology of these oxygen-blown vessels. The tuyere development work made possible and practical the bottom blowing of low-pressure oxygen at high flow rates through a series (typically eight) of tuyeres set in the bottom of the furnace. Each tuyere consists of a central pipe for the oxygen jet and an annular space for injecting a hydrocarbon (such as methane) to form a solid mushroom of steel (Fig. 6). This mushroom protects the refractory base from the fluxing effects of FeO and has allowed the revived use of the Bessemer vessel of 1856 (Ref 5), except that pure oxygen rather than air is injected.

Fig. 6 Thermal accretions (mushrooms) formed in Q-BOP steelmaking operations using the Savarde-Lee shrouded tuyere

The first North American licensee named this process the quick-quiet basic oxygen process, or Q-BOP. The bottom-blown oxygen jets provide better mixing, lower turndown carbons (of the order of 0.01 wt% C), higher yields (less FeO in slag), and shorter processing times (for example, 14 versus 17 min/blow). One drawback, however, is higher levels of turndown hydrogen in the steel. This is caused by the endothermic cracking of the methane that is needed for the formation of the protective thermal accretions, or mushrooms (Ref 6). Higher levels of dissolved hydrogen can be deleterious for heavy-section products such as pipeline steels and ship plate products; postrefining stir with argon is sometimes favored for steels with these applications.

Another feature of these bottom-blown vessels is the need to inject a fine powdered lime simultaneously with oxygen. Top charging of lime particles or lumps in a similar manner to BOF operations leads to unacceptable foaming and slopping.

A wide variety of other processes have been spawned that take advantage of some features of both top- and bottom-blown vessels. In the Kawasaki basic oxygen process (K-BOP) operation, 30% of the oxygen is soft blown from a multihole lance set high above the steel bath, with the remainder injected through the base of the vessel using shrouded tuyere technology. This allows low turndown carbons (of the order of 0.02 to 0.04% C), together with higher scrap-melting capabilities (for example, 33% versus 30% of the charge). Other similar technologies, such as the German Kloeckner metallurgy scrap (KMS) process, are also in use.

The improved scrap-melting capability of such vessels is enabled by the burning of a higher proportion of effluent carbon monoxide to carbon dioxide within the upper reaches of the vessel itself. Part of the attendant heat can be usefully transferred back to the metal bath, allowing more scrap to be melted. Because scrap generally represents a less expensive source of iron units versus hot metal from the blast furnace, such operations can be profitable, even though they are more technically complex to operate.

Practically all BOF (or oxygen-blown method (OBM) or Linze-Donovitz (LD) method) steelmaking operations in North America now use bottom-blown gas injections to at least stir the steel bath. For example, nitrogen, argon, or carbon dioxide can be blown through submerged injector ports, plugs, or nozzles of various proprietary designs. The Sumitomo top and bottom blowing (STB) process, in which CO_2/N_2 mixtures are bottom blown at about 5% of the flow of the top-blown oxygen in a BOF-like vessel, is a good example of this concept. The STB process increases yields and lowers turndown carbons, thus approaching the performance of Q-BOP vessels.

Electric Furnace Steelmaking. Although integrated steel plants use oxygen-blown steelmaking vessels, many smaller steelmaking operations rely on return scrap steel (versus iron ore) as a primary source of material. For such operations, electric arc furnaces offer economic and technological advantages. These furnaces were originally considered appropriate for the production of tool and alloy steels, but they are also able to produce low-carbon steels of high quality. Currently, 30% of the steel production in North America derives from scrap recycling through remelting and refining operations in electric arc furnaces. One difficulty is that residuals, such as copper and tin in return scrap, are not diluted with a virgin hot-metal source in electric furnace steelmaking. However, with the introduction of prereduced ores (Ref 7) of low range, or impurity levels (for example, $>2\%$ SiO_2) such problems can be mitigated.

Recent technological advances have stressed the role of the furnace as a melter rather than a refiner. Water-cooled panels are required to carry the ultrahigh-power kV A levels of modern furnaces.

Ferroalloy/Deoxidizer Additions. No matter which process is used, the raw steel poured from a furnace into a teeming ladle is too highly oxidized for immediate use because it contains about 0.04 to 0.1 wt% O. This level would cause blowholes in the steel if it were then solidified. Steel deoxidants such as aluminum, ferrosilicon, or carbon are therefore required to bring dissolved oxygen contents down to acceptable levels through precipitation of condensed oxides as inclusions. At the same time, additions of other ferroalloys (for example, Fe-Mn, Fe-Nb, Si-Mn, Fe-V) are made as needed to meet the chemical specifications required for the variety of steel grades that are commonly produced by any integrated steel company.

These bulk additions (13 to 100 mm, or $\frac{1}{2}$ to 4 in., in diameter) either melt quickly (~40 to 120 s) or dissolve slowly (~60 to 360 s), depending on whether their melting ranges are below or above the steel bath temperature (typically 1570 to 1600 °C, or 2860 to 2910 °F) (Ref 8). Some are buoyant (for example, aluminum and ferrosilicon) and tend to float, while others, such as ferroniobium and ferrotungsten, sink rapidly (Ref 1). In either case, thorough metal mixing throughout the teeming ladle is needed (Ref 1). These large bulk additions are commonly added via alloy addition chutes during the last half of a 4 to 8 min furnace-tapping operation. Carryover of slag from the BOF into the ladle can make the recoveries of aluminum and ferrosilicon to the steel highly variable because slag deoxidation as well as metal deoxidation can occur. For these reasons, alloy addition sequencing is important, as are slag control techniques, to limit the net carryover of slag.

Ladle Steelmaking. The increasing need to produce quality products that meet much tighter chemical and physical specifications has led to major changes in steelmaking practices during the last two decades. These changes have centered on modifications to liquid steel within the ladle; therefore, this area of technology is known as ladle steelmaking.

To illustrate the critical nature of correct chemistry, aluminum-killed steels for deep-drawing operations require dissolved aluminum levels that range between 0.03 and 0.04% $(\text{Al})_{\text{Fe}}$. The aluminum precipitates with dissolved nitrogen as aluminum nitride during subsequent batch-annealing operations. This precipitation controls grain growth and leads to steel with a fine grain structure and good deep-drawing qualities. Higher or lower levels of dissolved aluminum lead to poor performance indices (Fig. 7).

Fig. 7 Lankford index of aluminum-killed steels. Cold reduction 71.4%, anneal at 700 °C (1290 °F), 5h, furnace cool at 20 °C/h (36 °F/h)

Even tighter specifications were required for high-strength low-alloy steels, which were introduced to compensate for weight reductions (that is, thinner gages) on automobile parts during the energy crises of the 1970s. Specifications called for dissolved niobium levels of 0.03%, a difficult target without close control of steel deoxidation procedures.

The production of interstitial-free steels for deep drawing (which are described in the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume) require carbon and nitrogen levels less than 50 ppm and controlled additions of titanium and/or niobium to scavenge carbon and nitrogen. To meet such stringent demands, secondary steelmaking processes, focusing on the teeming ladle, have been developed. Of these, the ladle furnace is used for melt reheating and temperature control. The Ruhrstahl Hereaus (RH) degasser, or tank degasser, is used to reduce dissolved $(C, O, H, N)_{Fe}$ levels. A third type of ladle station provides strong stir facilities by using argon and porous plugs set in the base of each teeming ladle, slag rake-off equipment, and wire feeding that allows precise additions of alloying elements, such as aluminum.

Third-stage refining, although still novel, has been conducted by, among others, Sumitomo Metals Industries; it is also known as the injection refining (IR) process (Fig. 1). First lime and then calcium silicide are fed pneumatically through a vertical lance into the teeming ladle. A refractory-lined hood placed over the surface of the steel prevents ingress of atmospheric oxygen. As the relatively large lime particles rise through the melt, they cleanse it by collecting the essentially stationary smaller-diameter (~1 to 10 μm , or 40 to 400 $\mu in.$) products of deoxidation. The results of ternary refining are shown in Fig. 8. The number of clusters is greatly reduced after RH degassing followed by strong bubbling. The clusters are totally eliminated with strong bubbling and lime additions.

Fig. 8 Effect of lime powder injections on the quality of steel. RH, Ruhrstahl Hereaus process

A final injection of calcium silicide can be used to convert any remaining solid aluminum products of deoxidation into liquid calcium aluminate (preferably $12\text{CaO} \cdot 7\text{Al}_2\text{O}_3$) inclusions (Ref 9). Such inclusions pass easily through metering nozzles into the tundish and from there into the mold of a continuous casting machine.

By the end of these ladle-refining operations, the total residuals within the steel can be brought down to very low levels (~ 50 ppm total residuals for $(\text{S}, \text{O}, \text{N}, \text{H}, \text{P})_{\text{Fe}}$) (Ref 10). The difficulty in the final liquid metal processing steps is to maintain this level of physical and chemical quality prior to final solidification in the continuous casting machines.

Tundish Metallurgy and Continuous Casting. The flow of steel from the tundish into the caster is shown in Fig. 9. Figure 10 illustrates the potential sources of contamination of purified steel emptied from the teeming ladle into the tundish. Using a sliding gate nozzle, metal is metered from the bottom of the teeming ladle into a tundish. This nozzle has to be shrouded with argon to avoid air infiltration, steel reoxidation, and the consequent generation of inclusions.

Fig. 9 Typical continuous casting operation

Fig. 10 Potential sources of contamination in the continuous casting process

The tundish, in addition to acting as a metal distributor to two or more casters, serves as a further cleansing unit for inclusion removal. Therefore, current practices often use dam and weir combinations to modify the flow of steel within the tundish to enhance inclusion separation. This has led to a trend toward tundishes with larger volumes and thus longer residence times for a given throughput (for example, 60 tonne, or 66 ton, tundishes with a 7-min residence time for a 320 tonne, or 350 ton, ladle full of steel). A typical velocity field for a single-port water model tundish, using the computational fluid dynamic code METFLO (Ref 11), is illustrated in Fig. 11. The associated inclusion separation ratios (defined as the number of inclusions leaving per the number of inclusions entering a tundish) as a function of inclusion rise velocity are also given in Fig. 12. Flow modifiers have no influence on the very small inclusions collected by ternary refining (or by filters), but they can help clean the steel of midsize inclusions in the 50 to 200 μm (2 to 8 mils) range (Fig. 12). For larger inclusions with Stokes rising velocities greater than 5 mm/s (0.2 in./s), these flow controls are not needed for the set of operating conditions noted.

Fig. 11 Isometric view of flow fields predicted in a longitudinally bisected single-port water model slab casting tundish with a flow modification device consisting of a weir-dam arrangement placed at $\frac{2}{3}L$. Flow rate of $0.007 \text{ m}^3/\text{s}$ ($0.25 \text{ ft}^3/\text{s}$); length, 5.2 m (17 ft); depth, 111 m (3.6 ft); width (surface), 1.07 m (3.5 ft); flow modification device, $0.5L$ weir and dam arrangement

Fig. 12 Relationship between the inclusion separation ratio and Stokes rising velocities predicted for a full-scale water model of a slab casting tundish. FMD, flow-modification device consisting of a weir-dam arrangement (Fig. 11).

Tundishes are normally fitted with insulating covers to conserve heat. For highly deoxidized steels, they are protected with an argon gas cover to reduce reoxidation and inclusion formation. An artificial slag can also be added to absorb those inclusions that are floating out.

Contrary to popular belief, many inclusion clusters can reach large sizes within the tundish. Because they can be made up totally of alumina, large clusters are most likely the agglomerated products of deoxidation. Figure 13 presents data analyzing the large inclusions present in an aluminum-killed steel in a 60 tonne (66 ton) slab casting tundish not fitted with flow modifiers. A typical histogram of the inclusions, based on an on-line electric sensing technique using a Liquid Metal Cleanness Analyzer (LiMCA) (Ref 12), is compared with data from Japan for a wire quality steel (Ref 13). The slime extraction analysis technique (dissolution of large sample of steel by ferrous chloride, with elutriation to collect unreacted inclusions of alumina and/or silicates) was used for the Japanese data.

Fig. 13 Histogram of large inclusions in a slab casting tundish, based on the LiMCA technique, versus data for a wire quality steel, based on the slime extraction technique

Microscopic techniques are inappropriate for the size range shown in Fig. 13, and slime extraction techniques require three days to complete. Nevertheless, such analysis is important because large inclusions can have a deleterious effect on the surface quality, paintability, and zinc-coating characteristics of steel sheet. Similarly, as such inclusions (of alumina or manganese silicates, and so on) are rolled out into long stringers, the transverse properties of steel sheet or plate, such as percent elongation and ultimate tensile strength, are severely compromised, as is metal formability. Consequently, the

modification of these inclusions into calcium aluminate inclusions, which are refractory at rolling temperatures and retain their original spherical shape following rolling, is much preferred (Ref 9).

For other critical applications, the presence of inclusions with a diameter greater than about 50 μm (2 mils) needs to be prevented. Figure 14 shows a break in a steel wire fabricated for a steel-belted automobile tire (Ref 13). There is a move in the industry to filter steel for such applications to help eliminate inclusions under about 50 μm (2 mil) in size, which are not susceptible to flow modifiers.

Fig. 14 Scanning electron micrographs of inclusions at a break in a steel cord wire

Mold Metallurgy. The last opportunity for inclusions to be removed is in the mold. Metal enters the mold of a continuous caster through a submerged entry nozzle (Fig. 9); the ports of the nozzle are often angled upward in order to direct the exiting jets of metal up toward the steel surface. There, a layer of lubricating slag from fused mold powder further assimilates inclusions while it simultaneously protects the steel from reoxidation and provides lubrication between the forming shell of the steel and the surfaces of the oscillating mold.

It is preferred that the final structure of the solid steel be equiaxed rather than columnar so that cracking of the billet, slab, or bloom during unbending operations is less likely. Precise control of the metal super-heat temperature is needed to prevent dendrite tips that are broken from the advancing columnar freezing front of steel from remelting. The dendrite tips are needed to act as nuclei for grain growth within the remaining melt. Electromagnetic stirring is also used to enhance uniformity of chemistry and structure, and to eliminate center-line segregation of solute-rich material. The cast steel is then cut with travelling oxytorches into slabs, billets, or blooms of appropriate length for further processing. The slabs are about 4 m (13 ft) long, 1 m (3.3 ft) wide, and 100 mm (4 in.) thick. These slabs are inspected and then charged to a slab reheating furnace for subsequent hot-rolling operations. Alternatively, in plants with advanced steelmaking practices where slab surface quality is guaranteed to be acceptable (that is, no scarfing is required), the slabs can be directly charged into the slab reheat furnace.

Future Technology for Liquid Steel Processing Operations

Because of the high capital cost of the blast furnace, melt shop, and hot-rolling mill complex, major research and development efforts are being made within the industry, with the objective of eliminating the number of process steps needed to produce a final product. Figure 15 shows past, present, and possible future process steps for the production of flat-rolled sheet. The object is to reduce the number of major processes down to two: direct steelmaking and direct, or neat-net shape, casting. In direct steelmaking, the aim is to feed coal (rather than coke), together with iron ore pellets and lime flux, into an autogeneous reactor to produce iron that contains perhaps 2% C. In direct casting, the aim is to develop the technology needed to directly cast steel sheet perhaps 5 to 10 mm (0.2 to 0.4 in.) in thickness, at tonnage rates of 100 to 200 tonnes/h/m width (35 to 70 tons/h/ft width). Such performance characteristics would match those of the big slab

casters of the present, but would have a dramatic impact on the capital and operating costs of the integrated steel plant of the future.

Processing of Solid Steel

As with liquid steel, several processing operations are required to convert steel into its wide variety of finished form. Figure 15 shows the sequence of operations for flat rolling. After continuous casting and inspection, followed by slab reheating in the reheat furnace, the slab is prepared for the roughing and tandem hot strip mills. Rolled hot strip is then cooled on runout cooling tables and coiled. For thinner gages, hot-rolled strip is cold-rolled, which is followed by annealing and by various coating processes to protect against corrosion; coatings include zinc, tin, zincalume, paint, enamel, and so on. Slabs cut from the continuous casting machine are reheated to bring the steel to about 1200 °C (2190 °F).

Hot Rolling

Hot rolling is carried out with the steel in its γ , or austenite phase. Steel is evidently plastic and particularly malleable at the temperatures employed, which range from 1200 °C (2150 °F) to as low as 800 °C (1470 °F). This allows large reductions in thickness (for example, from 250 mm thick slab to 2 mm thick hot strip) with relatively small force. Following hot rolling, the steel transforms into its low-temperature α , or ferrite, phase (plus other constituents). The characteristics of this transformation, which has a significant effect on the mechanical properties of the product, depend on the cooling rates used on the runout cooling tables.

In early integrated steel mills, hot rolling traditionally began with the breakdown of cast ingots into rectangular slabs about 200 mm (8 in.) thick or square billets about 200 × 200 mm (8 × 8 in.) in cross section. With the gradual replacement of ingot casting by continuous casting (except for tool steels and other specialty or low-tonnage grades), the slabbing, or breakdown, stage of hot rolling has gradually disappeared from most mills. Layout of a modern hot strip mill is shown in Fig. 16. Hot rolling begins with roughing, which occurs at temperatures from 1200 °C (2190 °F) down to

about 1100 °C (2010 °F). During roughing, slabs about 6 to 8 m (20 to 26 ft) long and 250 mm (10 in.) thick are converted into transfer bars about 30 to 50 mm (1.2 to 1.2 in.) thick and up to 40 or 50 m (130 or 165 ft) long. Round or square billets are transformed by analogous steps into bars about 100 m (330 ft) in length. Finish rolling, or finishing, is then carried out in a five-, six-, or seven-stand hot mill (Fig. 16), with finishing stand temperatures as low as 900 or 800 °C (1650 or 1470 °F). By this means, the transfer bars are converted into strips about 2 to 3 mm. (0.08 to 0.12 in.) in thickness and 600 m (2000 ft) long, at a productivity level of about 100 tons/h per meter of steel strip width (Ref 14). The hot strip is coiled, while plate grades are retained in their rectangular form at thicknesses of about 10 to 30 mm (0.4 to 1.2 in.). In a similar manner, long products are either coiled if they are round and of small cross section (about 6 mm, or 0.24 in., in diameter), or cut to length if they are thicker or of irregular cross section, such as angle and channel shapes.

Controlled Rolling of Microalloyed Steels. The traditional concern of hot rolling was simply to reduce the cross-sectional size of the steel, as described above. However, with the use of microalloying elements such as niobium, vanadium, and/or titanium, hot-rolling at controlled temperatures is also used to condition the austenite so that a fine ferrite grain size is produced during cooling. This method of hot rolling, known as controlled rolling, relies on the precipitation of carbonitrides of the microalloying elements (niobium, vanadium, and/or titanium) to control austenite grain growth and recrystallization.

Over the last 20 years, there has been a gradual introduction of various types of controlled rolling (Ref 15), which presently include conventional controlled rolling, recrystallization controlled rolling, and dynamic recrystallization controlled rolling. With the various methods of controlled rolling, attractive properties can be imparted to materials in the as-hot-rolled condition, thereby eliminating the need for separate (and costly) heat treatment later. The use of controlled rolling leads to the production of steels with nearly twice the yield strength of the commodity grades produced by traditional rolling methods. This increase in yield strength is accompanied by an increase in fracture toughness (see the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume).

The increase in fracture toughness is a direct result of the considerable ferrite grain refinement caused by controlled rolling. Both the fracture properties and the yield strength depend directly on the inverse square root of the ferrite grain size, as given by the Hall-Petch relations (Ref 16):

$$\sigma_y = \sigma_0 + \kappa_y d^{1/2} \quad (\text{Eq 16})$$

and

$$\beta T = \alpha - \ln d^{1/2} \quad (\text{Eq 17})$$

where σ_y is the yield strength of the polycrystal, σ_0 is the yield strength of a single crystal of equivalent purity and condition, κ_y is the grain boundary strengthening coefficient, d is the mean grain size, T is the impact transition temperature, and α and β are constants. By reducing the ferrite grain size from 57 μm (2.25 mils), or ASTM grain size No.

5, for example, to 5 μm (0.2 mil), or ASTM grain size No. 12, yield strength increments of greater than 210 MPa (30 ksi) can be produced, and the impact transition temperature can be reduced by as much as 100 °C (180 °F).

Critical Temperatures. The three varieties of controlled rolling that have been developed to date rely on the recognition of the three critical temperatures of steel rolling. The first of the three temperatures is the no-recrystallization temperature, or T_{nr} . At temperatures above T_{nr} , the austenite recrystallizes between mill passes; as a result, the grain size is refined, and the work hardening accumulated within the roll pass is eliminated. This temperature can be detected by carrying out pilot rolling studies, by analyzing mill data on rolling loads, or by torsion testing (Fig. 17). Below the T_{nr} , the recrystallization of austenite no longer takes place between rolling passes. Work hardening, or strain, accumulates as a result, and the flow resistance or rolling load begins to increase more sharply with decreasing temperature (Fig. 17 and 18).

Fig. 17 Stress-strain curves of torsional simulation for an average schedule of a Steckel hot mill. The pass number is shown above each flow curve. Source: Ref 17

Fig. 18 Mean flow stress as a function of $1000/T$, where T is the absolute pass temperature. Region 1 corresponds to the temperature range where recrystallization occurs after each pass; region II falls between the no-recrystallization temperature and Ar_3 , the upper critical temperature; region III is the intercritical temperature range; region IV lies below the Ar_1 , of lower critical temperature. Source: Ref 17

The second critical temperature, the upper critical temperature, or Ar_3 , defines the start of the austenite-to-ferrite transformation on cooling (the *r* comes from the French *refroidissement*). The third temperature, the lower critical temperature, defines the end of the austenite-to-ferrite-plus pearlite transformation and is known as Ar_1 . It should be noted that these two critical temperatures do not correspond to the Ar_3 and Ar_1 values determined on annealed samples using classical dilatometry, for example, because the deformation introduced by rolling modifies the transformation behavior of the steel. Instead, Ar_3 and Ar_1 can be determined with the aid of a deformation dilatometer, which applies a compressive strain to the sample prior to the initiation of cooling, or by the torsion simulation of rolling (Fig. 17 and 18).

Precipitation of Carbonitrides and Sulfides. Many of the particles that are precipitated during cooling after continuous casting are redissolved during reheating in the slab reheat furnace. These include AlN , MnS , $Nb(C,N)$, $Ti(C,N)$, $Ti_4C_2S_2$, TiS , and VN . During subsequent hot rolling, these reprecipitate fairly readily because the dislocations introduced during rolling act as nucleation sites for strain-induced precipitation. These particles are only about 2.5 nm (0.1 μm .) in diameter when they appear, but they can grow or coarsen up to diameters of 10 to 20 nm (0.4 to 0.8 μm .) The particles take several seconds to form; therefore, they are not produced during rolling operations of short duration. In general, these particles only play a role at temperatures below 1000 °C (1830 °F); that is, during finishing. The strain-induced precipitation of MnS is important in the processing of electrical steels, while that of $Nb(C,N)$, $Ti_4C_2S_2$, and TiS is important in the rolling of interstitial-free steels, and that of $Nb(C,N)$ and to a lesser extent TiC and VN is important in the controlled rolling of microalloyed or high-strength low-alloy steels (Ref 15, 18).

Precipitation is necessary because recrystallization can only be arrested during finish rolling, and only if a copious number of precipitates form during passage of the strip between successive mill stands. A high density of precipitates is promoted by the occurrence of cooling between passes (which increases the driving force for precipitation) and interpass intervals of about 10 s or more. As a result, a T_{nr} is only displayed by steels containing niobium, titanium, or vanadium and, furthermore, only when sufficient time is provided during finish rolling for the precipitates to nucleate and grow (Ref 18). This means that recrystallization is most readily arrested during rolling in slow reversing mills, such as plate and Steckel mills, while precipitation plays a much smaller role in tandem mills, such as hot strip, rod, and other mill installations where interpass times are short ($\mu 0.5$ s or less).

Conventional controlled rolling (CCR) was the first type of controlled rolling to come into regular commercial use. About 8 to 10% of the total steel tonnage rolled annually is now produced in this way. This process was originally developed for the production of plate grades for the manufacture of oil and gas pipelines, for which the required minimum

yield strengths were 350 MPa (50 ksi), 420 MPa (60 ksi), and 490 MPa (70 ksi) (Ref 15). Because of the need for good weldability, low concentrations of carbon and carbon equivalents were specified. These were readily obtained by reducing carbon concentrations to 0.06 or 0.07%; small amounts of niobium (about 0.04%), in combination with vanadium (up to 0.1%) and molybdenum (up to 0.30%), were added for higher-strength grades.

During roughing operations, the coarse reheated austenite grains in a slab are first refined by repeated recrystallization, bringing the grain sizes down to about 20 μm (0.8 mil) or less. The transfer bar can then cool below the T_{nr} during transfer from roughing to the finishing facilities. When rolling is restarted or continued below the T_{nr} , recrystallization is no longer possible, and the austenite structure is progressively flattened in an operation known as pancaking. For pancaking to be successful, the accumulated reductions applied in this temperature range must add up to at least 80%. Finally, when the flattened austenite grains go through their transformation to ferrite, the ferrite produced has a very fine grain structure because of the large number of nucleation sites available on the expanded surfaces of the pancaked austenite grains. This leads to ferrite grain sizes in the range of 5 to 8 μm (0.2 to 0.3 mil). The fine-grain ferrite is responsible for the attractive combination of good toughness properties and high yield strengths (Ref 15, 18). It should be stressed that austenite pancaking is only possible in the absence of recrystallization, and its arrest is caused by the copious precipitation of Nb(C,N) during delays between mill passes.

Recrystallization Controlled Rolling (RCR). As described above, controlled rolling is generally based on the use of low finishing temperatures (that is, in the vicinity of 800 to 900 $^{\circ}\text{C}$, or 1470 to 1650 $^{\circ}\text{F}$), with the result that fine ferrite grain sizes appear after transformation. However, such finishing is inappropriate for certain products, such as heavy plates and thick-walled seamless tubes (Fig. 19), that cannot be finished at such low temperatures in the hot-rolling range due to excessive rolling loads. For such applications, it is possible to produce the fine microstructures required by carefully controlling the crystallization of austenite and arranging for it to occur at successively lower temperatures during finish rolling (Ref 19). These temperatures are nevertheless above 900 $^{\circ}\text{C}$ (1650 $^{\circ}\text{F}$) and thus are higher than those employed in CCR.

Fig. 19 Piercing stage in the manufacture of seamless tubes. Source: Ref 19

Two requirements must be met for the RCR process to be successful. One is that the recrystallization not be sluggish, so that the times required are not too long. This is achieved by employing vanadium rather than niobium as an alloying element. Vanadium acts as a grain refiner without bringing recrystallization to a complete stop, as niobium is inclined to do. The second requirement is that grain growth be prevented after each cycle of recrystallization; this grain growth can negate the refining effect of recrystallization at lower and lower temperatures. For this purpose, sufficient titanium is added to have about 0.01% available for the formation of fine particles of TiN during cooling after continuous casting (Ref 20). When this dispersion has an appropriate size and frequency distribution, it can completely prevent grain growth of the austenite after each cycle of recrystallization. The fine austenite grains, in turn, transform into relatively fine-grain ferrite, for example, 8 to 10 μm (0.3 to 0.4 mil) in diameter, leading to mechanical properties in the hot-rolled product that are acceptable for many purposes.

Dynamic Recrystallization Controlled Rolling (DRCR). When the interpass time is short, as in the case of rod, hot strip, and certain other rolling processes (Fig. 20), insufficient time is available for conventionally recrystallization during the interpass delay. The amount of carbonitride precipitation that can take place is also severely limited. As a result, an alternative form of recrystallization is initiated. This is known as dynamic recrystallization, and it involves the nucleation and growth of new grains during (as opposed to after) deformation (Ref 21, 22). This also requires the accumulation of appreciable reductions, of the order of 100%, to enable the recrystallization process to spread completely through the microstructure inherited from the roughing process. Austenite grain sizes as small as 10 μm (0.4 mil) can be achieved with DRCR (Ref 23).

Fig. 20 Finishing stands of a 2130 mm (84 in.) hot strip mill. Courtesy of Mesta Machine Company

Low-temperature finishing by DRCR has the advantage of producing finer ferrite grain sizes after transformation than CCR; that is, 3 to 6 μm (0.12 to 0.24 mil), as opposed to 5 to 8 μm (0.2 to 0.3 mil) for the latter process (Ref 21). However, such low-temperature finishing increases the rolling load, and it can also make mill control more difficult because of the load drop associated with the initiation of dynamic recrystallization. It is important to note that under industrial rolling conditions, CCR, RCR, and DRCR can all occur to different degrees during a given operation. This can happen when the processing parameters have not been optimized so as to favor only strain-induced precipitation and austenite pancaking in the case of CCR, conventional recrystallization in the case of RCR, and dynamic recrystallization in the case of DRCR.

The Stelco Coil Box. One of the problems associated with batch processes such as the rolling of both long and flat products is the temperature rundown that develops (between the head and tail of a transfer bar, for example). Such a gradual decrease in temperature can lead to gage and flatness problems, as well as to a gradient in microstructure characteristics (and therefore in the mechanical properties) along the workpiece. One solution to this problem has involved the introduction of a coil box between the roughing and finishing stands of a hot strip mill (Fig. 21). When the transfer bar, which is 30 to 50 mm (1.2 to 2 in.) thick, arrives at the coil box, the leading edge is deflected and curled into a circular shape, and the entire bar is wound into a coil without a mandrel or spool being required. The coiled shape of the workpiece enables it to cool much more slowly as the bar is slowly fed (tail end first) into the hot strip mill. This technology has led to a significant improvement in the uniformity of the dimensions and properties of the final product, as well as to a decrease in the energy required for hot rolling.

Fig. 21 Coil box of hot strip mill. (a) Position on delay table. (b) Schematic of coil box function. Source: Ref 14, 24

Cooling Beds, Runout Table Cooling, and Coiling. Following hot rolling, the workpiece is generally cooled down to room temperature. For plates and bars this is carried out on cooling beds. For strip it is carried out on runout tables and during holding, which follows coiling. Figures 22(a) and 22(b) show a laminar flow cooling system used on a hot mill. For rods it is carried out in water boxes and along cooling lines employing large volumes of forced air (Fig. 23). Except for certain grades of stainless and electrical steels, such cooling always involves the transformation of austenite into ferrite, as well as into a number of other transformation products, such as pearlite, bainite, and martensite. The particular transformation product that forms, as well as its general characteristics, depends on the cooling rate that is achieved. The faster the cooling rate within a given product range, the stronger the microstructure that is produced. As a result, there is considerable interest at present in the use of accelerated cooling to promote the formation of appropriate microstructures. For most steel products, in fact, this process is the least expensive way to increase the strength.

Fig. 22(a) Schematic showing the strip-cooling arrangement on a 2050 mm (82 in.) hot strip mill. See also Fig. 22(b). Source: Ref 14

Fig. 23 Arrangement of a processing line with retarded cooling. Courtesy of Morgan Construction Company

When the transformation product consists largely of ferrite, rapid cooling decreases the ferrite grain size obtained from a fixed hot-rolling schedule. This is because of the hysteresis involved in phase transformations, as a result of which the actual (as opposed to equilibrium) transformation temperature displayed on cooling decreases as the cooling rate is increased. Lower transformation temperatures, in turn, lead to finer ferrite grain sizes, in part because the growth rates are lower at lower temperatures, but also because the ferrite nucleus density increases with increasing supercooling below the equilibrium transformation temperature.

When the transformation product consists largely of pearlite or contains appreciable volume fractions of pearlite, more rapid cooling leads to the formation of finer pearlite, which is associated with higher-strength. However, if the cooling rate is too rapid for a given chemistry, some bainite or even martensite can form. Unless these transformations are carefully controlled, such structures lead to a lack of toughness and ductility and are therefore generally avoided. Nevertheless, B-modified bainitic steels are employed for the production of high-strength heavy plate (700 to 900 MPa, or 100 to 130 ksi, yield strength in the as-rolled condition); the carbon level in these steels is reduced to about 0.02% to improve toughness. Similarly, fully martensitic steels can be produced by quenching (a separate and therefore fairly expensive operation), in which case the brittleness is reduced by an appropriate tempering treatment.

Precipitation During Cooling and Coiling. The solubility of all the precipitate-forming elements in steel decreases as cooling progresses (Ref 18). Thus, carbonitrides and sulfides such as AlN, Fe₃C, MnS, Nb(C,N), Ti(C,N), Ti₄C₂S₂, TiS, and V(C,N) all tend to form, either on the runout table or cooling bed, or after coiling. Because precipitate nucleation and growth take time (for example, 1 to 10 s for nucleation, and 10 to 100 or 1000 s or more for growth, depending on the temperature), the amount and type of precipitation that takes place after hot rolling are sensitive functions of the cooling rate and conditions of holding. Thus, rapid cooling on the runout table suppresses precipitation, although some particles are inevitably formed during the austenite-to-ferrite transformation, because the solubilities in ferrite are appreciably lower than the respective levels that pertain to the austenite. The coiling temperature is also of considerable importance. Relatively high coiling temperatures, of the order of 750 °C (1380 °F), followed by the slow cooling rates associated with the geometry of coils, favor the precipitation of the carbonitrides (for example, AlN). Low coiling temperatures, of the order of 550 °C (1020 °F), on the other hand, prevent AlN formation and keep these elements in solution for precipitation during annealing after cold rolling. The coiling temperature also determines the mean size and number of the particles that form; the former decreases and the latter increases as the temperature is lowered. These considerations are important because the final grain size after recrystallization and grain growth is directly proportional to the mean particle size for a given chemistry (that is, containing a given volume fraction of precipitate).

Warm Rolling

In recent years a renewed interest has developed in warm rolling, that is, the finish hot rolling of steel in the high-ferrite, as opposed to the low-austenite, temperature range. Warm rolling is possible because ferrite is actually softer than austenite at a given hot-rolling temperature. From the example shown in Fig. 24 it is evident that the ferrite in an interstitial-free (IF) steel has as little as half the flow resistance of the austenite prior to transformation. Such a large difference in flow stress can lead to serious gage and control problems when rolling is carried out in the vicinity of the α -to- β transformation. These problems are avoided, however, if rolling is suspended during cooling through the intercritical range and resumed only when the steel has cooled below Ar₁.

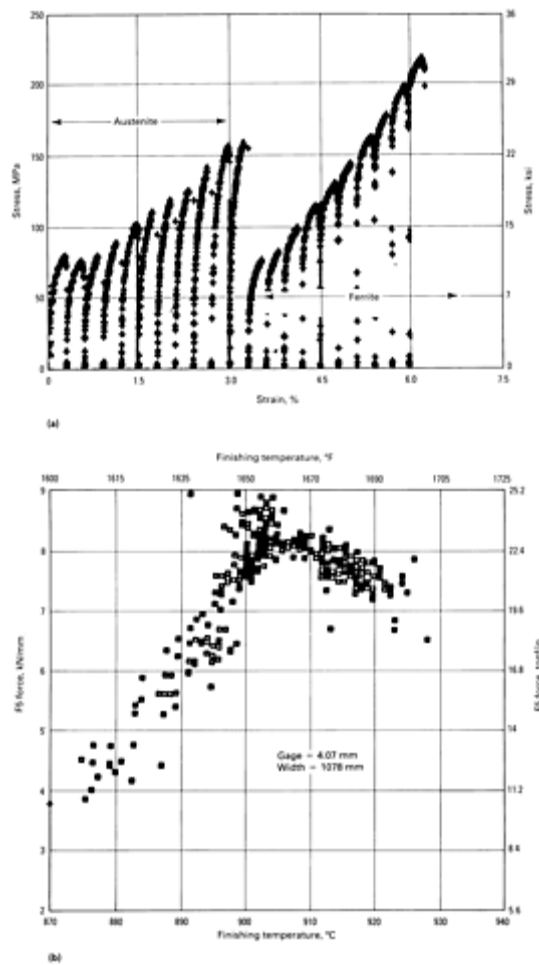

Fig. 24 Factors influencing the warm rolling of steel. (a) Stress-strain curves for interstitial-free steel rolled according to an idealized schedule A ($\epsilon \sim 2/s$). (b) Dependence of stand 5 separating force on rolling temperature. Source:Ref 25

The example given above is extreme because the low carbon level of an IF steel (about 30 ppm) means that the intercritical temperature range is reduced to as little as 30 °C (85 °F), and therefore the flow stress drop associated with passage through this range is very sharp. In conventional steels, the difference between the Ar_3 and Ar_1 temperatures is in the range of 100 °C (180 °F) or more. In such cases, the fully ferritic material is significantly colder than its fully austenitic counterpart, and thus the ferrite has a resistance to flow that is only moderately less than that of the austenite.

The warm rolling of IF steels is of commercial interest because lower reheating and rolling temperatures can be used, leading to lower scale losses and energy consumption rates in the slab reheat furnace. Furthermore, the textures developed during the warm rolling of ferrite do not differ appreciably from those produced during the cold rolling of the same phase, and this rolling step can therefore be employed for the production of steels with excellent formability characteristics.

Cold Rolling

About half of all rolled steel products are sold in the as-hot-rolled condition. This includes such obvious items as rails and structural sections (I beams, channels, angles, and so on), and plates and seamless tubes, as well as certain relatively thick grades of sheet and strip that are employed in the as-rolled condition (for example, for the forming of bumpers and car wheels, or for the manufacture of pipe). Nevertheless, numerous products require much more reduction in thickness or cross section and considerably better surface quality than can be produced by hot rolling; this is where cold rolling plays a role. In the cold rolling of flat products, numerous advances have been made in equipment and processes that have allowed for improved flatness and consistency of gage along the length of a coil. These advances include hydraulically

inflatable rolls for control of the amount of crown, six-high mills with tapered backup rolls that can be inserted and withdrawn laterally as required, as well as a variety of roll-bending techniques (Fig. 25).

Fig. 25 Taper-adjusting method for crown control. Source Ref 24

Cold rolling increases the hardness and yield strength, reduces the ductility and formability, and also introduces the specific texture components associated with thickness reduction at a constant width (known as plane-strain deformation) that can be later enhanced by annealing. Some products are sold and used in such a strengthened condition, particularly when little further deformation or shaping is involved. However, when appreciable further forming operations are to be carried out, such as in the manufacture of cans or the deep drawing of auto body parts, cold rolling must be followed by annealing. Annealing removes the work hardening introduced by rolling and thus restores the formability of the material. When employed after the appropriate processing of selected grades (for example, aluminum-killed drawing quality, also known as AKDQ, or IF steels), annealing also brings about an increase in the normal anisotropy (R value), which leads to significant further increases in the deep drawability.

Annealing

Batch Annealing. The annealing of coils weighing 9 to 27 tonnes (10 to 30 tons) is necessarily a very time-consuming operation. Typical heating and cooling times are of the order of 2 and 3 days, respectively, so that the rate of temperature change is about 12 °C/h (22 °F/h) during heating and -8 °C/h (-14 °F/h) during cooling. Consequently, a total process time of nearly 5 days is involved. Because of the considerable capital, maintenance, and energy costs associated with such heating operations (Fig. 23), the optimization of heating and cooling schedules to improve the productive capacity of these units is a subject of great interest at present.

The principal mechanism associated with batch annealing is recrystallization, which eliminates the strain hardening introduced in the previous rolling operations. Once initiated, at temperatures of 600 to 650 °C (1110 to 1200 °F), it takes only minutes to spread through the material and replace the grain structure flattened by rolling with equiaxed, strain-free grains. Although precipitate coarsening and particle solution and reprecipitation also occur, they are not of particular importance for most grades. For AKDQ steels, on the other hand, the characteristics of precipitation and of particle coarsening must be carefully controlled so that the grain orientations associated with high formability (that is, the $\{111\}<110>$ and to a lesser extent the $\{111\}<112>$ texture components) are favored during recrystallization and can in this way replace the other sets of grain orientations inherited from the rolling operation. This is brought about by pinning the undesirable $\{100\}$ -oriented grains during heating through their optimum growth temperature range by means of AlN

particles. These form during heating from the supersaturated Al and N held in solution as a result of the relatively low coiling temperatures (550 °C or 1020 °F) employed for the AKDQ grades. The AlN particles gradually redissolved and coarsen as the temperature is further increased during annealing, permitting growth of the {111}-oriented grains within the temperature range that favors this orientation.

Continuous Annealing. With the trend toward more and more continuous processing, batch annealing is gradually being replaced by continuous annealing (Fig. 26). The prime advantage of this process is the considerable increase in product uniformity along the length of a given coil. This is of increasing importance as tolerances and allowable property variabilities are reduced as a result of the increasing automatization of forming processes. Because of the much shorter process times involved (for example, 2 min instead of 5 days), the heating and cooling rates are much higher (15 °C/s, or 27 °F/s). Negligible hold times are required at the maximum temperatures of 700 to 800 °C (1290 to 1470 °F), which are significantly higher than in the batch annealing process.

Fig. 26 Examples of continuous annealing configurations. (a) Continuous annealing line. (b) Entry looping section. (c) Heating, holding, and cooling zones. Source: Ref 24

For commodity grades, the temperatures and heating and cooling rates are not of critical importance. By contrast, for drawing quality grades such as the niobium- and titanium-base IF steels, the process parameters must again be carefully adjusted for compatibility with the particular chemistries employed. For these steels, the favored texture components are {554}<225> and {111}<112> and, to a lesser extent, {111}<110>. These components differ slightly from those associated with the AKDQ steels and lead to still higher R values. As for the AKDQ grades, the appearance and disappearance of precipitates (in this case, Nb(C,N) and Ti₄C₂S₂), the mean sizes and volume fractions of these precipitates, and the amounts of niobium, titanium, carbon, and nitrogen remaining in solution must be carefully controlled if optimum product properties are to be produced. By tying up the carbon and nitrogen present in the form of carbonitrides and eliminating the yield drop in this way, low yield stresses are obtained, which lead to high initial work-hardening rates and n values. These, in association with the high R values that follow from the presence of the texture components described above, are responsible for the excellent drawability properties of these grades.

Introduction

THE PERFORMANCE of steels depends on the properties associated with their microstructures, that is, on the arrangements, volume fractions, sizes, and morphologies of the various phases constituting a macroscopic section of steel with a given composition in a given processed condition. Because all the phases in steels are crystalline, steel microstructures are made up of various crystals, sometimes as many as three or four different types, which are physically blended by solidification, solid-state phase changes, hot deformation, cold deformation, and heat treatment. Each type of microstructure and product is developed to characteristic property ranges by specific processing routes that control and exploit microstructural changes. Thus, processing technologies not only depend on microstructure but are also used to tailor final microstructures. For example, sheet steel formability depends on the single-phase ferritic microstructures of low-carbon cold-rolled and annealed steel, while high strength and wear resistance are enhanced by carefully developed microstructures of very fine carbides in fine martensite in fine-grain austenite of high-carbon hardened steels.

This article describes microstructures and microstructure-property relationships in steel. An important objective is to relate microstructural evolution to the different processing schedules to which various types of steel are subjected. For example, low-carbon sheet and plate steels are subjected to much different processing schedules and develop significantly different microstructures and properties from those of medium-carbon forged and hardened steels. This article emphasizes the correlation of microstructure and properties as a function of carbon content and processing in relatively low-alloy steels. More highly alloyed steels, such as tool steels and stainless steels, are discussed in detail in the Section "Specialty Steels and Heat-Resistant Alloys" in this Volume.

Iron-Carbon Phase Diagram

The major component of steel is iron, which exists in two crystal forms below its melting point. One is the body-centered cubic (bcc) form, which is stable from below room temperature to 912 °C (1675 °F) and from 1394 °C (2540 °F) to the

melting point of 1530 °C (2785 °F). In the former temperature range, bcc iron is known as α -ferrite, while in the higher temperature range, it is known δ -ferrite. The other crystal form, which is stable between 912 and 1394 °C (1675 and 2540 °F), is the face-centered cubic (fcc) form, known as austenite or γ -iron.

Steels also contain carbon in amounts ranging from very small, of the order of 0.005 wt% in ultralow-carbon, vacuum-degassed sheet steels, to a maximum of 2.00 wt% in the highest-carbon tool steels. Carbon profoundly changes the phase relationships, microstructure, and properties in steels. Generally, carbon content is kept low in steels that require high ductility, high toughness, and good weldability, but is maintained at higher levels in steels that require high strength, high hardness, fatigue resistance, and wear resistance.

Figure 1 shows the iron-carbon phase diagram and the changes that carbon induces in the phase equilibria of pure iron. Carbon is an austenite stabilizer and expands the temperature range of stability of austenite. Its solubility is much higher in austenite (a maximum of 2.11 wt% in equilibrium with cementite at 1148 °C, or 3000 °F) than in ferrite (a maximum of 0.0218 wt% in equilibrium with cementite at 727 °C, or 1340 °F). The solubility of carbon in ferrite and austenite is a function of temperature; when the carbon atoms can no longer be accommodated in the octahedral interstitial sites between the iron atoms, a new phase that can accommodate more carbon atoms in its crystal structure will form (Ref 2). This phase is designated as cementite or iron carbide (Fe_3C) and has an orthorhombic crystal structure. Cementite formation and the temperature-dependent solubility of carbon in austenite and ferrite, as controlled by alloying and processing, account for the great variety of microstructures and properties produced in steels.

Fig. 1 Iron-carbon equilibrium diagram up to 6.67 wt% C. Solid lines indicate Fe-Fe₃C diagram; dashed lines indicate iron-graphite diagram. Source: Ref 1

Alloys of iron and carbon that contain up to 2.00 wt% C are classified as steels, while those containing over 2.00 wt% C are classified as cast irons. Graphite is a more stable carbon-rich phase than cementite; its formation is promoted by a high carbon concentration and the presence of large amounts of such elements as silicon. Therefore, graphite is an important phase in cast irons but is rarely found in steels. When graphite does form, solubility limits and temperature ranges of phase stability are changed slightly, as indicated by the dashed lines in Fig. 1.

The austenite phase field shown in Fig. 1 is the basis for the hot workability and heat treatability of carbon steels. Single-phase austenite is readily hot worked; therefore, massive sections of steel can be hot reduced to smaller sections and structural shapes. Austenite, upon cooling, must transform to other microstructures. If slow cooled under conditions approximating equilibrium, austenite will change to mixtures of ferrite and cementite (Fig. 1); if cooled rapidly, it will change to martensite. Such transformations provide the basis of the heat treatments applied to steels. Thus, the fortuitous high-temperature stability of austenite in iron and iron-carbon alloys and the solid-state transformation of austenite upon

cooling create many opportunities to optimize shape, section size, microstructure, and properties for many different applications.

Processing temperatures for the formation and transformation of austenite are set by the critical temperatures that mark the boundaries between the various phase fields of Fig. 1. The critical temperatures as a function of carbon content, which were initially identified by changes in slope or thermal arrests in heating and cooling curves, are given the designation "A." If equilibrium conditions apply, the designations A_{e1} , A_{e3} and $A_{e_{cm}}$, or simply A_1 , A_3 , and A_{cm} , are used to indicate the upper boundary of the ferrite-cementite phase field, the boundary between the ferrite-austenite and austenite phase fields, and the boundary between the austenite and austenite-cementite phase fields (Fig. 1). If heating conditions apply (which raise the critical temperatures relative to equilibrium), then A_{c1} , A_{c3} , and $A_{c_{cm}}$ are used for the critical temperatures, with the c being derived from the French *chauffant*. If cooling conditions apply (which lower critical temperatures relative to equilibrium), then the designations A_{r1} , A_{r3} , and $A_{r_{cm}}$ are used, with the r being derived from the French *refroidissant*. There is hysteresis in the transformation temperatures (that is, A_c temperatures are higher than A_e temperatures and A_r temperatures are lower than A_e temperatures) because continuous heating and cooling leave insufficient time for complete diffusion-controlled transformation at the true equilibrium temperatures.

In addition to iron and carbon, steels contain many other elements that shift the boundaries of the iron-carbon phase diagram. Elements such as manganese and nickel are austenite stabilizers, which lower critical temperatures. Elements such as silicon, chromium, and molybdenum are ferrite stabilizers and carbide formers, which raise critical temperatures and shrink the austenite phase field (Ref 3). Other elements, such as titanium, niobium, and vanadium, may form temperature-dependent dispersions of nitrides, carbides, or carbonitrides in the austenite. These effects must be taken into account when setting processing temperature ranges for commercial alloys. For well-established grades, the optimum temperature ranges for hot work are listed in Ref 4.

Carbon Content and Properties

Figure 2 shows hardness as a function of carbon content for various types of microstructures. Hardness is readily measured and generally is directly proportional to strength and inversely proportional to ductility and toughness. Although the hardness-carbon relationships are shown as lines in Fig. 2, they are in fact better represented as bands because many factors may cause variations in hardness in a given microstructure. For example, the strength of low-carbon ferritic microstructures is very sensitive to grain size, while that of largely pearlitic microstructures is very sensitive to the interlamellar spacing of cementite and ferrite.

Fig. 2 Hardness as a function of carbon content for various microstructures in steels. Crosshatched area shows effect of retained austenite. Source: Ref 1

All types of microstructures increase in strength with increasing carbon content, but martensitic microstructures show the most dramatic increases. Because of the low solubility of carbon in ferrite (except for as-quenched martensite), the carbon is primarily concentrated in carbide phases. Therefore, much of the higher strength of medium- and high-carbon steels is due to higher volume fractions and finer dispersions of carbides in ferrite. Ferritic matrix grain sizes and morphology also significantly affect mechanical behavior at any given carbon level.

Figure 2 shows that all types of microstructures could be produced in a steel of a given carbon content. There are, however, practical limits to this observation. Low-carbon steels do not have sufficient hardenability to form martensite except in the thinnest sections and are therefore produced primarily with ferritic microstructures, which have excellent ductility for cold-working and forming operations. At the other extreme, medium- and high-carbon steels alloyed with chromium, nickel, and/or molybdenum may have such high hardenability for the formation of martensite or bainite that other microstructures are formed only by special annealing treatments.

The preceding comments should help explain why various types of steels have evolved based on the most readily attainable microstructures and the property requirements that they satisfy for certain types of applications. Alloy design and processing approaches have also evolved and are still evolving to exploit the best features of each type of steel. The following sections in this article describe in detail several important ferrous microstructures and the steels and processing methods used to produce them.

Pearlite and Bainite

Pearlite is the name given to the microstructure produced from austenite (A) during cooling of a steel by the following solid-state reaction:

Such a reaction, in which one solid phase transforms to two other solid phases, is generically termed a eutectoid reaction. In the case of steels, the ferrite (F) and cementite (Fe_3C) form as roughly parallel lamellae, or platelets, to produce a composite lamellar two-phase structure. Figure 3 shows an example of pearlite formed in a rail steel that contains close to the eutectoid carbon content, 0.77 wt%C. In this scanning electron micrograph the cementite lamellae appear light and ferrite appears recessed because it has etched more deeply than the cementite.

Fig. 3 Scanning electron micrograph showing pearlite in a rail steel eutectoid composition. Courtesy of F. Zia-Ebrahimi

The parallel lamellae act as diffraction gratings in the light microscope and diffract light of various wavelengths to produce the colors and the luster characteristic of pearls. Thus, early metallographers used the name pearlite for the unique lamellar structure they observed in steels. Within a given colony of pearlite, it has been shown that all the ferrite and cementite have largely the same crystallographic orientations. Therefore pearlite may be described as two interpenetrating single crystals (Ref 5).

Under equilibrium conditions, best approximated by very slow cooling, the pearlite reaction must occur at 727 °C (1340 °F), because austenite is not stable below that temperature (Fig. 1). However, pearlite formation is accomplished by diffusion, a time-dependent process. Carbon atoms diffuse away from regions that become ferrite to regions that become cementite. Thus, rapid cooling, which gives less time for diffusion, depresses pearlite formation to lower temperatures.

Figure 4 shows an isothermal transformation diagram for 1080 steel, which contains 0.79 wt% C and therefore transforms entirely to pearlite over a range of temperatures well below 727 °C (1340 °F). Figure 4 was produced by cooling the steel rapidly to a series of temperatures below A_1 , holding at those temperatures, and then following, as a function of time, the transformation of austenite to pearlite. An incubation time is required for the initiation of transformation, and this time, as shown by the curve that marks the beginning of transformation, decreases with decreasing temperature. This acceleration is associated with increased undercooling, which provides greater thermodynamic driving force, increasing nucleation rates and decreasing interlamellar spacing. The latter, in turn, enhances growth rates because of reduced diffusion distances.

Fig. 4 Isothermal transformation diagram for 1080 steel containing 0.79 wt% C and 0.76 wt% Mn. Specimens were austenitized at 900 °C (1650 °F) and had an austenitic grain size of ASTM No. 6. The M_s , M_{50} , and M_{90} temperatures are estimated. Source: Ref 1

The kinetics of pearlite formation, based on the nucleation and growth of spherical pearlite colonies, are described by (Ref 6):

$$f(t) = 1 - \exp \left[- \pi N G^3 t^4 / 3 \right] \quad (\text{Eq 2})$$

where $f(t)$ is the volume fraction of pearlite formed at any time t at a given temperature, N is the nucleation rate of the colonies, and G is the growth rate of the colonies. Equation 2 describes well the slow initial and final transformation rates and the more rapid intermediate transformation rates observed for isothermal pearlite formation. With decreasing temperature below A_1 , N and G increase, and the transformation of austenite to pearlite accelerates, as shown in Fig. 4.

During pearlite formation, in addition to carbon atom diffusion, iron atoms must also transfer across the interface between the austenite and pearlite. This short-range iron atom transfer is necessary to accomplish the crystal structure changes among the austenite, ferrite, and cementite. At a critical low temperature, this atom-by-atom short-range diffusion is no longer possible, and the iron atoms accomplish the crystal structure change by shearing or cooperative displacement (Ref 7). This change in transformation mechanism results in a new type of microstructure, referred to as bainite. The ferrite crystals assume elongated morphologies, and the cementite is no longer continuous and lamellar (Ref 8).

The bainite that forms at temperatures just below those at which pearlite forms (Fig. 4) is termed upper bainite. In medium- and high-carbon steels, it typically consists of groups of ferrite laths with coarse cementite particles between the

laths. The bainite that forms at lower temperatures is termed lower bainite and consists of large needlelike plates that contain high densities of very fine carbide particles. Figures 5 and 6 show examples of upper and lower bainite, respectively. In these micrographs the bainite morphology is dominated by the ferrite phase, and the carbides are too fine to be resolved by the light microscope. In some low- and medium-carbon steels (generally, those alloyed with manganese, molybdenum, and silicon), bainitic microstructures with ferrite and austenite (or martensite formed from the austenite) will form instead of the classic ferrite-carbide bainitic structures (Ref 9).

Proeutectoid Ferrite and Cementite

Steels with a lower carbon content than the eutectoid composition (hypoeutectoid) steels) and a higher carbon content than the eutectoid composition (hypereutectoid steels) form ferrite and cementite, respectively, prior to pearlite. The structures formed upon cooling between A_{r3} and A_{r1} , and A_{cm} and A_{r1} are referred to as proeutectoid ferrite and proeutectoid cementite, respectively.

Figure 7 shows a low-carbon steel ferrite-pearlite microstructure that formed during air cooling from the austenite phase field (Fig. 1). The sequence of transformation to this microstructure is described below. When the temperature of the specimen reaches the A_{r3} temperature, proeutectoid ferrite begins to form. The ferrite crystals, or grains, as they are referred to by metallurgists, nucleate on austenite grain boundaries and grow, by rearrangement of iron atoms, from the fcc austenite structure into the bcc ferrite structure at the austenite-ferrite interface. Carbon atoms, because of their low solubility in the ferrite, are rejected into the untransformed austenite. When the steel reaches the A_{r1} temperature, most of the microstructure has transformed to proeutectoid ferrite, and the carbon content of the remaining austenite has been enriched to about 0.77 wt%, which is exactly the composition required for the pearlite reaction. Thus, the balance of the austenite transforms to pearlite, as described in the preceding section.

Fig. 7 Light micrograph showing microstructure of proeutectoid ferrite (white) and pearlite (dark) in a 0.17C-1.2Mn-0.19Si steel

In Fig. 7, the ferrite appears white, and the boundaries between ferrite grains of different orientation appear as dark lines. The pearlite, in contrast to Fig. 3, appears uniformly black because the interlamellar spacing of the pearlite in this example is too fine to be resolved by the light microscope.

Figure 8 shows an example of proeutectoid cementite in a hypereutectoid steel. The cementite has formed as a thin network along the grain boundaries of the austenite, and the balance of the microstructure is martensite, which formed when the specimen was quenched from a temperature between A_{cm} and A_1 . The cementite and its interfaces are preferred sites for fracture initiation and propagation, and as a result, proeutectoid cementite networks make hypereutectoid steels extremely brittle. Intercritical annealing treatments that break up and spheroidize the cementite are therefore used to increase toughness.

section sizes and equipment design, the austenite transforms to microstructures of ferrite and pearlite. Depending on the casting technique, some steel products undergo several cycles of austenite to ferrite-pearlite transformation, as shown in Fig. 9. Each step in a cycle requires the nucleation and growth of new phases and offers the possibility of controlling grain size and the distribution of various microstructural components.

Traditionally, hot working has been used to reduce large ingots to products with reduced cross sections and special shapes, but there has been little attempt to control microstructure other than the use of slightly reduced finish hot-rolling temperatures. This approach has been substantially modified in recent years by the implementation of two major changes in process design: the casting of smaller and smaller sections, and the use of hot rolling to control microstructure and properties as well as to reduce section size.

The progression of casting technology from ingot to continuous (or strand) to thin slab to direct strip casting is shown in Fig. 9. Continuous casting eliminates the soaking and breakdown hot rolling of large ingots. Thin slab casting eliminates the roughing hot work applied to thick slabs that are produced by either ingot or continuous casting. Direct strip casting, which is still under development, would eliminate all hot work (Ref 10). A considerable savings of time and energy and improved surface quality result from the new casting techniques.

The control of microstructure and properties during hot-rolling involves a thermomechanical processing technique known as controlled rolling. Controlled rolling is used to enhance the toughness and strength of microalloyed low-carbon plate and strip steels by grain refinement (see Ref 11, 12, 13 and the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume). The fine grain sizes produce significantly increased strength, from the 210 MPa (30 ksi) yield strengths that are typical of conventionally hot-rolled low-carbon steels to yield strengths between 345 and 550 MPa (50 and 80 ksi).

The key to the use of controlled rolling is the formation of fine austenite grains that transform upon cooling to very fine ferrite grains. Deformation of austenite induces strains, which, at high temperatures, are rapidly eliminated by recrystallization, followed by grain growth of the austenite. However, at low deformation temperatures, grain growth is considerably retarded. If the temperature is low enough, even recrystallization is suppressed, especially in steels to which small amounts of alloying elements such as niobium have been added. The niobium, which is soluble at high temperatures, precipitates out as fine niobium carbonitrides at low austenitizing temperatures. These fine precipitate particles stabilize the deformation substructure of the deformed austenite and prevent recrystallization. Upon cooling, ferrite grains nucleate on the closely spaced grain boundaries of the unrecrystallized austenite and form very fine grain microstructures.

A number of thermomechanical processing schedules have been developed to produce low-carbon steels of high strength and toughness. Figure 10 shows schematically a number of treatments developed by Japanese steelmakers (Ref 12). Similar controlled rolling schedules are used worldwide to produce fine-grain low-carbon steels. A processing parameter introduced in Fig. 10 is the austenite recrystallization temperature (T_R , which is primarily dependent on the amount of deformation and alloying).

Fig. 10 Temperature-time schedules for thermomechanical processing of steels. (a) Normal processing. (b) Controlled rolling of carbon-manganese steel. (c) Controlled rolling of niobium-containing steel, finishing above A_{c3} . (d) Controlled rolling of niobium-containing steel, finishing below A_{c3} . Source: Ref 11

Controlled rolling is generally performed on microalloyed high-strength low-alloy (HSLA) steels, which have small amounts (generally less than 0.10%) of carbide- and nitride-forming elements such as niobium, titanium, and/or vanadium. The various microalloying elements have different temperature-dependent solubility products (Ref 11, 13), and hot-rolling parameters must be adjusted to fit specific alloy compositions (see the section "Controlled Rolling" in the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume).

Processing: Ferritic Microstructure

Large tonnages of hot-rolled steel strip are further processed to produce highly deformable sheet. As shown in Fig. 11, processing involves cold rolling to reduce thickness and improve surface quality, followed by annealing to produce microstructures consisting of ductile ferrite grains (Ref 14, 15). Cold-rolled and annealed sheet steels have low carbon contents, usually less than 0.10%, and therefore contain little pearlite in the slow-cooled hot-rolled condition. However, if pearlite is present, it is deformed during cold rolling, and the cementite of the pearlite rapidly spheroidizes during annealing as the strained, cold-rolled ferrite recrystallizes to unstrained, equiaxed grains. These microstructural changes are shown in Fig. 12 for a 0.08% C steel containing 1.5% Mn and 0.21% Si (Ref 16).

Fig. 12 Light micrographs of a 0.08C-1.5Mn-0.21Si steel. (a) After cold rolling 50%. (b) After cold rolling 50% and annealing at 700 °C (1290 °F) for 20 min. Source: Ref 16

A recently developed type of steel, made possible by the introduction of vacuum degassing into the steelmaking process, contains very low carbon, less than 0.008% (Ref 17). These steels are referred to as interstitial-free or ultralow-carbon steels and may contain small additions of niobium or titanium to tie up nitrogen and carbon residual from the steelmaking process. Interstitial-free steels have excellent deep-drawing properties (see the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume). The carbon content of the interstitial-free steels is below that of the solubility limit of carbon in bcc ferrite (Fig. 1 and 13); therefore, no pearlite forms in these steels. Also, the low interstitial content and the addition of stabilizing elements such as titanium or niobium eliminate strain aging and quench aging, as discussed below.

Fig. 13 Iron-rich side of Fe-C diagram showing extent of ferrite-phase field and decrease of carbon solubility in ferrite with decreasing temperature. Source: Ref 1

The formability of cold-rolled and annealed sheet steels, especially in stamping operations that require deep drawing, is significantly improved by the development of crystallographic textures that defer necking and fracture in thin sheets to higher strains. The preferred orientations, {111} planes parallel to the plane of the sheets and <110> directions in the rolling direction (that is, {111} <110> annealing textures), are promoted by aluminum deoxidation. The aluminum-killed steels, if finish hot rolled at high temperatures and coiled at low temperatures, retain aluminum and nitrogen in solid solution in hot-rolled strip and through cold rolling (Ref 15). During batch annealing, aluminum nitride particles precipitate and suppress the nucleation and growth of recrystallized grains in orientations other than the preferred orientations for good formability.

The traditional method of annealing cold-rolled sheet has been to heat stacks of coils in a batch process (Fig. 11). Batch annealing requires several days. Recently, continuous annealing lines, in which the sheet is uncoiled and rapidly passed through high-temperature zones in continuous annealing furnaces, have been installed and used to anneal cold-rolled sheet steels (Ref 14). Continuous annealing requires only minutes to recrystallize a section of sheet as it passes through the hot zone of a furnace.

Although cold-rolled and annealed sheet steels have low carbon contents, during annealing at temperatures close to the A_1 temperature, some carbon and nitrogen are always taken into solution (unless the steels are ultralow-carbon or interstitial-free steels). Figure 13 shows the carbon-rich side of the Fe-C diagram. Carbon has its maximum solubility at the A_1 temperature, and its solubility decreases with temperature to a negligible amount at room temperature. Nitrogen shows a similar relationship. Thus, if a steel is cooled from around A_1 at a rate that prevents gradual relief of supersaturation by cementite formation during cooling, the ferrite at room temperature may be highly supersaturated with respect to carbon and nitrogen. These interstitial elements then may segregate to dislocations in strained structures, a process referred to as strain aging, or they may precipitate out as fine carbide or nitride particles, a process referred to as quench aging (Ref 15). The aging processes may occur at room temperature or during heating at temperatures just above room temperature because of the high diffusivity of carbon and nitrogen in the bcc ferrite structure.

Strain aging and quench aging raise the yield strength of ferritic microstructures by pinning dislocations. When yielding does occur, new dislocations are generated and the stress drops to a lower level at which localized plastic deformation propagates across a specimen. The localized deformation is referred to as a Lüders band, and the process is described as discontinuous yielding. In deformed sheet steels, Lüders bands are called stretcher strains and, if present, result in unacceptable surface appearance in formed parts. In order to eliminate stretcher strains, cold-rolled and annealed sheet steels are temper rolled (Fig. 11). The temper rolling introduces just enough strain to exceed the Lüders strain. Beyond this point, sufficient dislocations are introduced, and all parts of a specimen or deformed sheet will strain uniformly or continuously.

Continuously annealed sheet steels are very susceptible to aging effects, because the thin sheet cools rapidly from the annealing temperature in contrast to batch annealing. As a result, various types of overaging treatments are applied to continuously annealed steels, as shown in Fig. 11. These treatments are designed to remove carbon and nitrogen from solid solution by the precipitation of relatively coarse carbide and nitride particles.

Most cold-rolled steels are subcritically annealed; that is, they are annealed below the A_1 temperature. However, continuous annealing lines have made possible intercritical heating into the ferrite-austenite field, with cooling that is rapid enough to cause the austenite to transform to martensite. The martensite formation introduces a dislocation density exceeding that which can be pinned by the available carbon. As a result, early yielding is continuous and occurs with high rates of strain hardening. Intercritically annealed steels with ferrite-martensite microstructures are referred to as dual-phase steels and offer another approach to producing high strength levels that range from 345 to 550 MPa (50 to 80 ksi) in low-carbon steels (Ref 18, 19, 20). Dual-phase steels are discussed in the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume.

Martensite

Martensite is the phase that produces the highest hardness and strength in steels (Fig. 2). The martensitic transformation is diffusionless and occurs upon cooling at rates rapid enough to suppress the diffusion-controlled transformation of

austenite to ferrite, pearlite, and bainite. Neither the iron atoms nor the carbon atoms diffuse. Therefore, the transformation occurs by shearing or the cooperative motion of large numbers of atoms. Figure 14 shows schematically the formation of a martensitic crystal. Macroscopically, the shears act parallel to a fixed crystallographic plane, termed the habit plane, and produce a uniformly tilted surface relief on a free surface. Not only is the crystal structure change from austenite (fcc) to martensite (bcc) (referred to as the lattice deformation) accomplished by the transformation, but also the product martensite is simultaneously deformed because of the constraints created by maintaining an unrotated and undistorted habit plane within the bulk austenite (Ref 2, 21). The deformation of the martensite is referred to as the lattice invariant deformation, and it produces a high density of dislocations or twins in martensite. This fine structure, together with the carbon atoms trapped within the octahedral interstitial sites of the body-centered tetragonal structure, produce the very high strength of as-quenched martensite (Ref 22).

Fig. 14 Schematic of shear and surface tilt associated with the formation of a martensite plate. Courtesy of M.D. Geib

Martensite begins to form at a critical temperature, defined as the martensite start (M_s) temperature. The transformation is accomplished by the nucleation and growth of many crystals. Because of the matrix constraints, the width of the martensitic units is limited, and the transformation proceeds primarily by the successive nucleation of new crystals. This process occurs only upon cooling to lower temperatures and is therefore independent of time. The latter type of transformation kinetics is termed athermal and is characterized by (Ref 23):

$$f = 1 - \exp - [0.01] (M_s - T_q) \quad (\text{Eq 3})$$

where f is the fraction of martensite formed after quenching to any temperature, T_q , below M_s . Thus, the amount of martensite that forms at room temperature, for example, is a function only of M_s .

The M_s temperature is a function of the carbon and alloy content of steel, and a number of equations from which M_s can be calculated based on composition have been developed (Ref 2). Figure 15 shows that M_s decreases sharply with increasing carbon content in iron-carbon alloys. Almost all other alloying elements also lower M_s . A major effect of low M_s temperatures is incomplete martensite formation at room temperature. Therefore, in all martensitic structures, some austenite is retained, the exact amount of which depends sensitively on composition.

Fig. 15 M_s temperature as a function of carbon content in steels. Composition ranges of lath and plate martensite in iron-carbon alloys are also shown. Source: Ref 2; investigations referenced are identified by their number in that reference.

Two morphologies of martensitic microstructures form in iron-carbon alloys and steels (Fig. 15). In low- and medium-carbon alloys, lath martensite forms. Lath martensite is characterized by parallel board or lath-shaped crystals. The laths have an internal structure consisting of tangled dislocations, and the microstructure contains small amounts of retained austenite between the laths. The groups of parallel laths are termed packets; many of the laths are too fine to be resolved in the light microscope. Figure 16 shows an example of lath martensite in 4340 steel.

Fig. 16 Light micrograph of lath martensite in 4340 steel quenched from 940 °C (1725 °F) and tempered at 350 °C (660 °F). Packets of parallel laths are below resolution of light microscope. Source: Ref 24

In high-carbon steels, plate martensite forms. The martensitic crystals have the shape of plates, and adjacent units tend to be nonparallel. The fine structure associated with the plates often consists of fine transformation twins, and large amounts

of retained austenite are present because of the low M_s temperatures. Figure 17 shows plate martensite and austenite in an Fe-1.36C alloy.

Fig. 17 Light micrograph of plate martensite and retained austenite in an Fe-1.39C alloy. Source: Ref 25

Martensite can form only if the diffusion-controlled transformations of austenite can be suppressed. On a practical level, this is accomplished by rapid quenching, for example, in water or brine baths. However, such drastic cooling introduces high surface tensile residual stresses and may cause quench cracking. Therefore, medium-carbon steels are alloyed with elements such as nickel, chromium, and molybdenum, which make it more difficult for the diffusion-controlled transformations to occur. As a result, martensite can be formed with less drastic cooling, such as oil quenching. The design of steels and cooling conditions to produce required amounts of martensite is the subject of the technology referred to as hardenability (Ref 26, 27).

The application of hardenability concepts characterize not only the conditions that produce martensite but also those under which other microstructures form. Thus, hardness gradients in bars of various diameters, cooled at various rates, can be estimated. Continuous cooling diagrams, in which cooling conditions that produce various microstructures are defined for a given steel, are often related to hardness gradients measured on Jominy end-quenched specimens, as shown in Fig. 18.

Fig. 18 Continuous transformation and isothermal transformation for steel containing nominally 0.4% C, 1.0% Cr, and 0.2% Mo. Several cooling rates are related to positions and hardness on a Jominy end-quench specimen. Source: Ref 1

Tempering of Martensite

As-quenched martensite has very high strength, but has very low fracture resistance, or toughness. Therefore, almost all steels that are quenched to martensite are also tempered, or heated, to some temperature below A_1 in order to increase toughness. Depending on time and temperature, tempering treatments can produce a wide variety of microstructures and properties.

As-quenched martensitic microstructures are supersaturated with respect to carbon, have high residual stresses, contain a high density of dislocations, have a very high lath or plate boundary area per unit volume, and contain retained austenite. All these factors make martensitic microstructures very unstable and drive various phase transformations and microstructural changes during tempering. Table 1 lists the various reactions that develop during tempering. The most important changes are a result of aging and precipitation phenomena, which are caused by the supersaturation of carbon, and range from carbon atom clustering to transition carbide precipitation to cementite formation and spheroidization. Figure 19 shows a plate of high-carbon martensite tempered at 150 °C (300 °F). The dark basketweave structure is due to contrast associated with rows of very fine particles that are 2 nm (0.08 $\mu\text{in.}$) in size, of the orthorhombic transition carbide, η . The carbides must be imaged by other techniques (Ref 29, 30). Tempering at temperatures between 150 and 200 °C (300 and 390 °F) retains high hardness with increased toughness relative to as-quenched martensite.

Table 1 Tempering reactions in steel

Temperature range		Reaction and symbol (if designated)	Comments
°C	°F		
-40 to 100	-40 to 212	Clustering of two to four carbon atoms on octahedral sites of martensite (A1); segregation of carbon atoms to dislocations and boundaries	Clustering is associated with diffuse spikes around fundamental electron diffraction spots of martensite
20 to 100	70 to 212	Modulated clusters of carbon atoms on (102) martensite planes (A2)	Identified by satellite spots around electron diffraction spots of martensite
60 to 80	140 to 175	Long period ordered phase with ordered carbon atoms (A3)	Identified by superstructure spots in electron diffraction patterns
100 to 200	212 to 390	Precipitation of transition carbide as aligned 2 nm (0.08 $\mu\text{in.}$) diam particles (T1)	Recent work identifies carbides as η(orthorhombic, Fe_2C); earlier studies identified the carbides as ϵ(hexagonal, $\text{Fe}_{2.4}\text{C}$).
200 to 350	390 to 660	Transformation of retained austenite to ferrite and cementite (T2)	Associated with tempered-martensite embrittlement in low- and medium-carbon steels

250 to 700	480 to 1290	Formation of ferrite and cementite; eventual development of well-spheroidized carbides in a matrix of equiaxed ferrite grains (T3)	This stage now appears to be initiated by χ-carbide formation in high-carbon Fe-C alloys.
500 to 700	930 to 1290	Formation of alloy carbides in chromium-, molybdenum-, vanadium- and tungsten-containing steels. The mix and composition of the carbides may change significantly with time (T4).	The alloy carbides produce secondary hardening and pronounced retardation of softening during tempering or long-time service exposure around 500 °C (930 °F).
350 to 550	660 to 1020	Segregation and cosegregation of impurity and substitutional alloying elements	Responsible for temper embrittlement

Source: Ref 28

Fig. 19 Transmission electron micrograph showing effects of transition carbide precipitation (dark contrast) in fine structure of a plate of martensite in an Fe-1.22C alloy tempered at 150 °C (300 °F). Source: Ref 29

Tempering at higher temperatures causes the formation of cementite, and, if strong carbide-forming elements are present, alloy carbides. Concurrently, the laths or plates coarsen and the dislocation density is reduced by recovery mechanisms (Ref 2). In addition, retained austenite transforms to mixtures of cementite and ferrite between martensite laths and plates. The carbides formed by high-temperature tempering are much coarser than the transition carbides and are present at residual martensite interfaces and dispersed within the ferrite of the tempered martensite (Fig. 20).

Fig. 20 Transmission electron micrograph showing the microstructure of 4130 steel water quenched from 900 °C (1650 °F) and tempered at 650 °C (1200 °F) Courtesy of F. Woldow

Figure 21 shows the range of hardness levels which may be obtained by tempering at various temperatures as a function of the carbon content of the steel. The highest hardnesses for engineering applications are associated with the transition carbide microstructures produced by tempering at 150 °C (300 °F). These microstructures have excellent fatigue and wear resistance and are used for such applications as shafts, gears, and bearings. The lowest hardnesses are associated with microstructures of spheroidized carbides in a matrix of equiaxed ferrite. Steels with these microstructures are used when very high toughness or corrosion resistance (for example, resistance to H₂S in oil field applications) is required.

Fig. 21 Hardness as a function of carbon content in iron-carbon alloys quenched to martensite and tempered at various temperatures. Source: Ref 31

Toughness, or fracture resistance, generally increases with tempering temperature, but various types of embrittlement or reduced toughness can develop (Ref 2). Figure 22 shows impact toughness as a function of tempering temperature for selected sets of steels with high and low levels of phosphorus. Carbon content has a major influence on toughness. Medium-carbon tempered steels are quite tough, but high-carbon steels show very low impact toughness, which limits the

application of hardened and tempered high-carbon steels to conditions of compressive loading without impact, such as in bearings. The effect of carbon on the toughness of low-temperature tempered specimens correlates with increasing densities of transition carbides and associated high strain hardening rates as carbon content increasing (Ref 2).

Fig. 22 Charpy V-notch impact toughness as a function of tempering temperature for various alloy steels. High phosphorus levels are about 0.02% and low phosphorus levels range between 0.002 and 0.009%. Source: Ref 32, 33

Toughness reaches its peak in specimens tempered at 200 °C (390 °F); it drops to a minimum in specimens tempered around 300 °C (570 °F). This drop is referred to as tempered martensite embrittlement and is associated with the transformation of retained austenite to coarse carbide structures. Tempered martensite embrittlement is exacerbated by phosphorus segregation to prior-austenite grain boundaries and carbide interfaces, but this effect appears to be constant over the entire tempering range (Fig. 22). At higher tempering temperatures, between 350 and 550 °C (660 and 1020 °F), another embrittlement phenomenon may develop in steels containing phosphorus, antimony, or tin (Ref 34). This embrittlement is referred to as temper embrittlement, and requires long holding times or slow cooling through the embrittling temperature range. Alloy steels are most susceptible, and the cosegregation of the alloying elements with the impurities to prior austenite grain boundaries has been documented (Ref 35).

Processing: Quenched and Tempered Microstructures

Hardened steels with tempered martensitic microstructures are most frequently used in machine components that require high strength and excellent fatigue resistance under conditions of cyclic loading. Figure 23 shows a typical processing sequence for these components. Hot-rolled bars are received and forged, generally at high temperatures where deformation into complex shapes is readily accomplished. The forgings are air cooled, and ferrite-pearlite microstructures develop upon cooling to room temperature. A normalizing treatment to refine the coarse microstructures that originated because of high-temperature forging may be required, or a spheroidizing treatment to produce a microstructure of ferrite and spheroidized cementite may be applied if extensive machining prior to hardening is required. The forgings are then austenitized, quenched to martensite, and tempered to the properties described in the preceding section. Straightening and stress relieving operations may be applied if required.

Fig. 23 Temperature-time processing schedules for producing quench and tempered forgings

Processing: Direct-Cooled Forging Microstructures

To reduce the number of processing steps associated with producing quenched and tempered microstructures, new alloying approaches have been developed to produce high-strength microstructures directly during cooling after forging. Figure 24 shows a schematic of such a processing approach and an alternate processing sequence that cold finishes hot-rolled bars. Eliminating heat treatment processing steps by direct cooling relative to quenching and tempering has obvious advantages.

Fig. 24 Temperature-time schedule for producing direct-cooled forgings and cold-finished bars

One group of steels that has been developed for direct cooling is microalloyed medium-carbon steels (see Ref 36, 37 and the article "High-Strength Low-Alloy Steel Forgings" in this Volume). These steels contain small amounts of vanadium and niobium and transform to precipitation-hardened microstructures of ferrite and pearlite. The hardness produced by rapid air cooling ranges from 25 to 30 HRC depending on the extent of precipitation and pearlite in the microstructure; ultimate strength values are over 690 MPa (100 ksi). Thus, the hardness and strength levels are not as high as can be produced by quenching and low-temperature tempering, but they are more than adequate for many automotive applications that require intermediate strengths (Ref 36).

The fatigue resistance of direct-cooled microalloyed steels is comparable to that of quenched and tempered steels of the same hardness, but the impact toughness is much lower. This reduced toughness is due to the well-known increase in the ductile-to-brittle transition temperature in steels with ferrite-pearlite microstructures as pearlite content increases (Fig. 25). In order to improve the toughness of direct-cooled forging steels, steels that transform to bainitic structures and forging steels with lower carbon concentrations and finer ferrite-pearlite microstructures are being developed (Ref 38).

Fig. 25 Impact transition curves as a function of carbon content in normalized steels. Increase in ductile-to-brittle transition temperatures with increasing carbon content is due to increasing amounts of pearlite. Source: Ref 1

Summary

This article has briefly described the major microstructures and the phase transformations by which these microstructures are developed in carbon and low-alloy steels. Each type of microstructure and product is developed to characteristic property ranges by specific processing routes that control and exploit microstructural changes. The incorporation of steel carbon content into microstructure has a profound effect on microstructure and properties, and steels fall naturally into low-strength/high ductility/high toughness or high-strength/high fatigue resistant/low toughness groups with increasing carbon content. The use of new casting techniques, microalloying, and thermomechanical processing are being used increasingly to reduce processing steps and to improve steel product microstructures and quality.

Introduction

STEELS constitute the most widely used category of metallic material, primarily because they can be manufactured relatively inexpensively in large quantities to very precise specifications. They also provide a wide range of mechanical properties, from moderate yield strength levels (200 to 300 MPa, or 30 to 40 ksi) with excellent ductility to yield strengths exceeding 1400 MPa (200 ksi) with fracture toughness levels as high as 110 MPa \sqrt{m} (100 ksi \sqrt{in}).

This article will review the various systems used to classify carbon and low-alloy steels*, describe the effects of alloying elements on the properties and/or characteristics of steels, and provide extensive tabular data pertaining to designations of

steels (both domestic and international). More detailed information on the steel types and product forms discussed in this article can be found in the articles that follow in this Section.

Note

- * The term low-alloy steel rather than the more general term alloy steel is being used to differentiate the steels covered in this article from high-alloy steels. High-alloy steels include steels with a high degree of fracture toughness (Fe-9Ni-4Co), which are described in the article "Ultrahigh-Strength Steels" in this Section of the Handbook. They also include maraging steels (Fe-18Ni-4Mo-8Co), austenitic manganese steels (Fe-1C-12Mn), tool steels, and stainless steels, which are described in separate articles in the Section "Specialty Steels and Heat-Resistant Alloys" in this Volume.

Classification of Steels

Steels can be classified by a variety of different systems depending on:

- *The composition*, such as carbon, low-alloy, or stainless steels
- *The manufacturing methods*, such as open hearth, basic oxygen process, or electric furnace methods
- *The finishing method*, such as hot rolling or cold rolling
- *The product form*, such as bar, plate, sheet, strip, tubing, or structural shape
- *The deoxidation practice*, such as killed, semikilled, capped, or rimmed steel
- *The microstructure*, such as ferritic, pearlitic, and martensitic (Fig. 1)
- *The required strength level*, as specified in ASTM standards
- *The heat treatment*, such as annealing, quenching and tempering, and thermomechanical processing
- *Quality descriptors*, such as forging quality and commercial quality

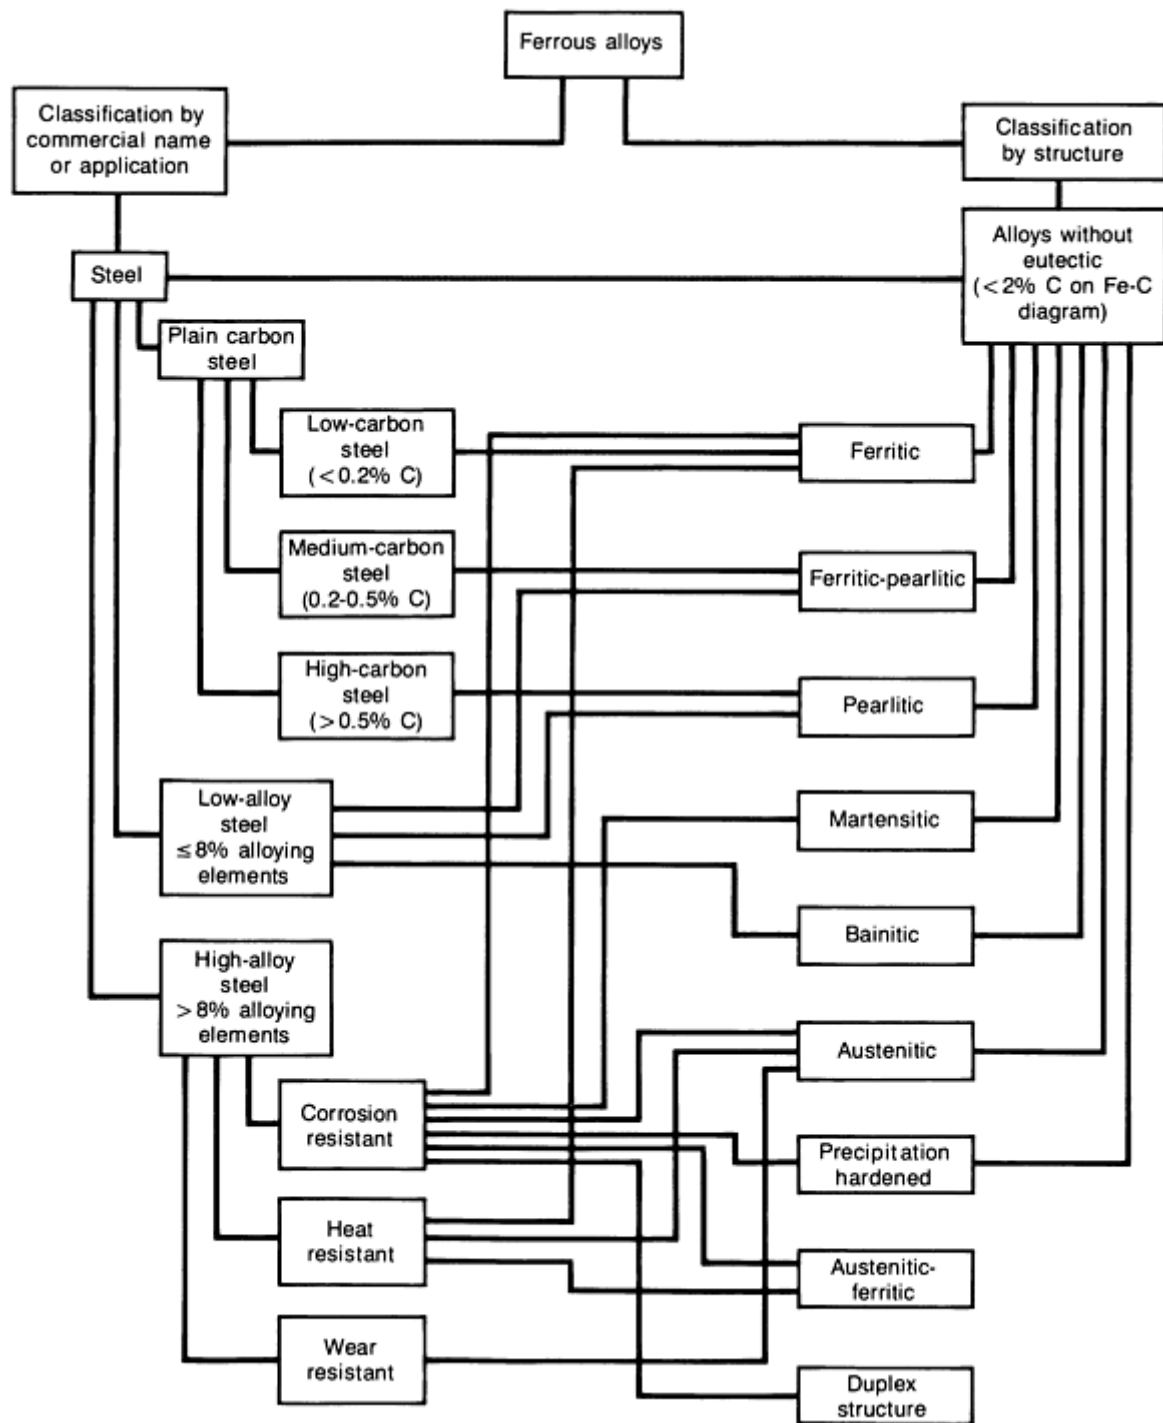

Fig. 1 Classification of steels. Source: D.M. Stefanescu, University of Alabama, Tuscaloosa

Of the aforementioned classification systems, chemical composition is the most widely used internationally and will be emphasized in this article. Classification systems based on deoxidation practice and quality descriptors will also be reviewed. Information pertaining to the microstructural characteristics of steels can be found in the article "Microstructures, Processing, and Properties of Steels" in this Volume and in *Metallography and Microstructures*, Volume 9 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Chemical Analysis

Chemical composition is often used as the basis for classifying steels or assigning standard designations to steels. Such designations are often incorporated into specifications for steel products. Users and specifiers of steel products should be familiar with methods of sampling and analysis.

Chemical analyses of steels are usually performed by wet chemical analysis methods or spectrochemical methods. Wet analysis is most often used to determine the composition of small numbers of specimens or of specimens composed of machine tool chips. Spectrochemical analysis is well-suited to the routine determination of the chemical composition of a large number of specimens, as may be necessary in a steel mill environment. Both classical wet chemical and spectrochemical methods for analyzing steel samples are described in detail in *Materials Characterization*, Volume 10 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Heat and Product Analysis. During the steelmaking process, a small sample of molten metal is removed from the ladle or steelmaking furnace, allowed to solidify, and then analyzed for alloy content. In most steel mills, these heat analyses are performed using spectrochemical methods; as many as 14 different elements can be determined simultaneously. The heat analysis furnished to the customer, however, may include only those elements for which a range or a maximum or minimum limit exists in the appropriate designation or specification.

A heat analysis is generally considered to be an accurate representation of the composition of the entire heat of metal. Producers of steel have found that heat analyses for carbon and alloy steels can be consistently held within ranges that depend on the amount of the particular alloying element desired for the steel, the product form, and the method of making the steel. These ranges have been published as commercial practice, then incorporated into standard specifications. Standard ranges and limits of heat analyses of carbon and alloy steels are given in Tables 1, 2, 3, and 4.

Table 1 Carbon steel cast or heat chemical limits and ranges

Applicable only to semifinished products for forging, hot-rolled and cold-finished bars, wire rods, and seamless tubing

Element	Maximum of specified element, %	Range, %
Carbon ^(a)	≤ 0.12	...
	>0.12-0.25 incl	0.05
	>0.25-0.40 incl	0.06
	>0.40-0.55 incl	0.07
	>0.55-0.80 incl	0.10
	>0.80	0.13
Manganese	≤ 0.40	0.15
	>0.40-0.50 incl	0.20
	>0.50-1.65 incl	0.30
Phosphorus	>0.040-0.08 incl	0.03

	>0.08-0.13 incl	0.05
Sulfur	>0.050-0.09 incl	0.03
	>0.09-0.15 incl	0.05
	>0.15-0.23 incl	0.07
	>0.23-0.35 incl	0.09
Silicon (for bars) ^{(b)(c)}	≤ 0.15	0.08
	>0.15-0.20 incl	0.10
	>0.20-0.30 incl	0.15
	>0.30-0.60 incl	0.20
Copper	When copper is required, 0.20% minimum is commonly used	
Lead^(d)	When lead is required, a range of 0.15-0.35 is generally used	

Note: Boron-treated fine-grain steels are produced to a range of 0.0005-0.003% B. Incl, inclusive.

Source: Ref 1

- (a) The carbon ranges shown customarily apply when the specified maximum limit for manganese does not exceed 1.10%. When the maximum manganese limit exceeds 1.10%, it is customary to add 0.01 to the carbon range shown.
- (b) It is not common practice to produce a rephosphorized and resulfurized carbon steel to specified limits for silicon because of its adverse effect on machinability.
- (c) When silicon is required for rods the following ranges and limits are commonly used: 0.10 max; 0.07-0.15, 0.10-0.20, 0.15-0.35, 0.20-0.40, or 0.30-0.60.
- (d) Lead is reported only as a range of 0.15-0.35% because it is usually added to the mold or ladle stream as the steel is poured.

Table 2 Carbon steel cast or heat chemical limits and ranges

Applicable only to structural shapes, plates, strip, sheets, and welded tubing

Element	Maximum of specified element, %	Range, %
Carbon ^{(a)(b)}	≤ 0.15	0.05

	>0.15-0.30 incl	0.06
	>0.30-0.40 incl	0.07
	>0.40-0.60 incl	0.08
	>0.60-0.80 incl	0.11
	>0.80-1.35 incl	0.14
Manganese	≤ 0.50	0.20
	>0.050-1.15 incl	0.30
	>1.15-1.65 incl	0.35
Phosphorus	≤ 0.08	0.03
	>0.08-0.15 incl	0.05
Sulfur	≤ 0.08	0.03
	>0.08-0.15 incl	0.05
	>0.15-0.23 incl	0.07
	>0.23-0.33 incl	0.10
Silicon	≤ 0.15	0.08
	>0.15-0.30 incl	0.15
	>0.30-0.60 incl	0.30
Copper	When copper is required, 0.20% minimum is commonly specified	

Incl, inclusive.

Source: Ref 1

- (a) The carbon ranges shown in the range column apply when the specified maximum limit for manganese does not exceed 1.00%. When the maximum manganese limit exceeds 1.00%, add 0.01 to the carbon ranges shown in the table.

(b) Maximum of 0.12% C for structural shapes and plates.

Table 3 Alloy steel heat composition ranges and limits for bars, blooms, billets, and slabs

	0.80-1.15 incl	0.20	0.20
Vanadium	≤ 0.25	0.05	0.05
	>0.25-0.50 incl	0.10	0.10

Note: Boron steels can be expected to contain a minimum of 0.0005% B. Alloy steels can be produced with a lead range of 0.15-0.35%. A heat analysis for lead is not determinable because lead is added to the ladle stream while each ingot is poured. Incl, inclusive.

Source: Ref 3

Because segregation of some alloying elements is inherent in the solidification of an ingot, different portions will have local chemical compositions that differ slightly from the average composition. Many lengths of bar stock can be made from a single ingot; therefore, some variation in composition between individual bars must be expected. The compositions of individual bars might not conform to the applicable specification, even though the heat analysis does. The chemical composition of an individual bar (or other product) taken from a large heat of steel is called the product analysis or check analysis. Ranges and limits for product analyses are generally broader and less restrictive than the corresponding ranges and limits for heat analyses. Such limits used in standard commercial practice are given in Tables 5, 6, and 7.

Table 5 Product analysis tolerances for carbon and alloy steel plates, sheet, piling, and bars for structural applications

Element	Upper limit or maximum specified value, %	Tolerance, %	
		Under minimum limit	Over maximum limit
Carbon	≤ 0.15	0.02	0.03

(a) Resulturized steels are not subject to product analysis limits for sulfur.

(b) If the minimum of the range is 0.01%, the under tolerance is 0.005%.

(c) Tolerances shown apply only to 0.065 m² (100 in.²) or less.

(d) Tolerance is over and under.

Residual elements usually enter steel products from raw materials used to produce pig iron or from scrap steel used in steelmaking. Through careful steelmaking practices, the amounts of these residual elements are generally held to acceptable levels. Sulfur and phosphorus are usually considered deleterious to the mechanical properties of steels; therefore, restrictions are placed on the allowable amounts of these elements for most grades. The amounts of sulfur and

phosphorus are invariably reported in the analyses of both carbon and alloy steels. Other residual alloying elements generally exert a lesser influence than sulfur and phosphorus on the properties of steel. For many grades of steel, limitations on the amounts of these residual elements are either optional or omitted entirely. Amounts of residual alloying elements are generally not reported in either heat or product analyses, except for special reasons.

Silicon Content of Steels. The composition requirements for many steels, particularly plain carbon steels, contain no specific restriction on silicon content. The lack of a silicon requirement is not an omission, but instead indicates recognition that the amount of silicon in a steel can often be traced directly to the deoxidation practice employed in making it (further information can be found in the section "Types of Steel Based on Deoxidation Practice" in this article).

Rimmed and capped steels are not deoxidized; the only silicon present is the residual amount left from scrap or raw materials, typically less than 0.05% Si. Specifications and orders for these steels customarily indicate that the steel must be made rimmed or capped, as required by the purchaser, restrictions on silicon content are not usually given.

The extent of rimming action during the solidification of semikilled steel ingots must be carefully controlled by matching the amount of deoxidizer with the oxygen content of the molten steel. The amount of silicon required for deoxidation may vary from heat to heat. Thus, the silicon content of the solid metal can also vary slightly from heat to heat. A maximum silicon content of 0.10% is sometimes specified for semikilled steel, but this requirement is not very restrictive; for certain heats, a silicon addition sufficient to leave a residue of 0.10% may be enough of an addition to kill the steel.

Killed steels are fully deoxidized during their manufacture; deoxidation can be accomplished by additions of silicon, aluminum, or both, or by vacuum treatment of the molten steel. Because it is the least costly of these methods, silicon deoxidation is frequently used. For silicon-killed steels, a range of 0.15 to 0.30% Si is often specified, providing the manufacturer with adequate flexibility to compensate for variations in the steelmaking process and ensuring a steel acceptable for most applications. Aluminum-killed or vacuum-deoxidized steels require no silicon; a requirement for minimum silicon content in such steel is unnecessary. A maximum permissible silicon content is appropriate for all killed plain carbon steels; a minimum silicon content implies a restriction that the steel must be silicon killed. Silicon is intentionally added to some alloy steels, for which it serves as both a deoxidizer and an alloying element to modify the properties of the steel. An acceptable range of silicon content would be appropriate for these steels.

Users and specifiers of steel mill products must realize that the silicon content of these items cannot be established independently of deoxidation practice. In ordering mill products, it is often desirable to cite a standard specification (such as an ASTM specification) where the various ramifications of restrictions on silicon content have already been considered in preparing the specification. In some instances, such as the forming of low-carbon steel sheet, the choice of deoxidation practice can significantly affect the performance of the steel; in such cases, it is appropriate to specify the desired practice.

Types of Steel Based on Deoxidation Practice (Ref 3)

Steels, when cast into ingots, can be classified into four types based on the deoxidation practice employed or, alternatively, by the amount of gas evolved during solidification. These types are killed, semikilled, rimmed, or capped steels (Fig. 2).

Fig. 2 Eight typical conditions of commercial steel ingots, cast in identical bottle-top molds, in relation to the degree of suppression of gas evolution. The dotted line indicates the height to which the steel originally was poured in each ingot mold. Depending on the carbon and, more importantly, the oxygen content of the steel, the ingot structures range from that of a fully killed ingot (No. 1) to that of a violently rimmed ingot (No. 8). Source: Ref 5

Killed steel is a type of steel from which there is only a slight evolution of gases during solidification of the metal after pouring. Killed steels are characterized by more uniform chemical composition and properties as compared to the other types. Alloy steels, forging steels, and steels for carburizing are generally killed.

Killed steel is produced by various steel-melting practices involving the use of certain deoxidizing elements which act with varying intensities. The most common of these are silicon and aluminum; however, vanadium, titanium, and zirconium are sometimes used. Deoxidation practices in the manufacture of killed steels are normally left to the discretion of the producer.

Semikilled steel is a type of steel wherein there is a greater degree of gas evolution than in killed steel but less than in capped or rimmed steel. The amount of deoxidizer used (customarily silicon or aluminum) will determine the amount of gas evolved. Semikilled steels generally have a carbon content within the range of 0.15 to 0.30%; they are used for a wide range of structural shape applications.

Semikilled steels are characterized by variable degrees of uniformity in composition, which are intermediate between those of killed and rimmed steels. Semikilled steel has a pronounced tendency for positive chemical segregation at the top-center of the ingot (Fig. 2).

Rimmed Steels. In the production of rimmed steels, no deoxidizing agents are added in the furnace. These steels are characterized by marked differences in chemical composition across the section and from the top to the bottom of the ingot (Fig. 2). They have an outer rim that is lower in carbon, phosphorus, and sulfur than the average composition of the whole ingot, and an inner portion, or core, that has higher levels than the average of those elements. The typical structure of the rimmed steel ingot results from a marked gas evolution during solidification of the outer rim.

During the solidification of the rim, the concentration of certain elements increases in the liquid portion of the ingot. During solidification of the core, some increase in segregation occurs in the upper and central portions of the ingot. The structural pattern of the ingot persists through the rolling process to the final product (rimmed ingots are best suited for steel sheets).

The technology of manufacturing rimmed steels limits the maximum content of carbon and manganese, and those maximums vary among producers. Rimmed steels do not retain any significant percentages of highly oxidizable elements such as aluminum, silicon, or titanium.

Capped steels have characteristics similar to those of rimmed steels but to a degree intermediate between those of rimmed and semikilled steels. A deoxidizer may be added to effect a controlled rimming action when the ingot is cast. The gas entrapped during solidification is in excess of that needed to counteract normal shrinkage, resulting in a tendency for the steel to rise in the mold. The capping operation limits the time of gas evolution and prevents the formation of an excessive number of gas voids within the ingot.

Mechanically capped steel is cast in bottle-top molds using a heavy metal cap.

Chemically capped steel is cast in open-top molds. The capping is accomplished by adding aluminum or ferrosilicon to the top of the ingot, causing the steel at the top surface to solidify rapidly. The top portion of the ingot is discarded.

The capped ingot practice is usually applied to steel with carbon contents greater than 0.15% that is used for sheet, strip, wire, and bars.

Quality Descriptors

The need for communication among producers and between producers and users has resulted in the development of a group of terms known as fundamental quality descriptors. These are names applied to various steel products to imply that the particular products possess certain characteristics that make them especially well suited for specific applications or fabrication processes. The fundamental quality descriptors in common use are listed in Table 8.

Table 8 Quality descriptions of carbon and alloy steels

Carbon steels
Semifinished for forging
Forging quality
Special hardenability
Special internal soundness
Nonmetallic inclusion requirement
Special surface
Carbon steel structural sections
Structural quality
Carbon steel plates
Regular quality
Structural quality
Cold-drawing quality
Cold-pressing quality
Cold-flanging quality
Forging quality
Pressure vessel quality
Hot-rolled carbon steel bars

Merchant quality
Special quality
Special hardenability
Special internal soundness
Nonmetallic inclusion requirement
Special surface
Scrapless nut quality
Axle shaft quality
Cold extrusion quality
Cold-heading and cold-forging quality
Cold-finished carbon steel bars
Standard quality
Special hardenability
Special internal soundness
Nonmetallic inclusion requirement
Special surface
Cold-heading and cold-forging quality
Cold extrusion quality
Hot-rolled sheets
Commercial quality

Drawing quality
Drawing quality special killed
Structural quality
Col-rolled sheets
Commercial quality
Drawing quality
Drawing quality special killed
Structural quality
Porcelain enameling sheets
Commercial quality
Drawing quality
Drawing quality special killed
Long terme sheets
Commercial quality
Drawing quality
Drawing quality special killed
Structural quality
Galvanized sheets
Commercial quality
Drawing quality
Drawing quality special killed

Lock-forming quality
Electrolytic zinc coated sheets
Commercial quality
Drawing quality
Drawing quality special killed
Structural quality
Hot-rolled strip
Commercial quality
Drawing quality
Drawing quality special killed
Structural quality
Cold-rolled strip
Specific quality descriptions are not provided in cold-rolled strip because this product is largely produced for specific end use
Tin mill products
Specific quality descriptions are not applicable to tin mill products
Carbon steel wire
Industrial quality wire
Cold extrusion wires
Heading, forging, and roll-threading wires
Mechanical spring wires
Upholstery spring construction wires

Welding wire
Carbon steel flat wire
Stitching wire
Stapling wire
Carbon steel pipe
Structural tubing
Line pipe
Oil country tubular goods
Steel specialty tubular products
Pressure tubing
Mechanical tubing
Aircraft tubing
Hot-rolled carbon steel wire rods
Industrial quality
Rods for manufacture of wire intended for electric welded chain
Rods for heading, forging, and roll-threading wire
Rods for lock washer wire
Rods for scrapless nut wire
Rods for upholstery spring wire
Rods for welding wire

Alloy steels
Alloy steel plates
Drawing quality
Pressure vessel quality
Structural quality
Aircraft physical quality
Hot-rolled alloy steel bars
Regular quality
Aircraft quality or steel subject to magnetic particle inspection
Axle shaft quality
Bearing quality
Cold-heading quality
Special cold-heading quality
Rifle barrel quality, gun quality, shell or A.P. shot quality
Alloy steel wire
Aircraft quality
Bearing quality
Special surface quality
Cold-finished alloy steel bars
Regular quality
Aircraft quality or steel subject to magnetic particle inspection

Axle shaft quality
Bearing shaft quality
Cold-heading quality
Special cold-heading quality
Rifle barrel quality, gun quality, shell or A.P. shot quality
Line pipe
Oil country tubular goods
Steel specialty tubular goods
Pressure tubing
Mechanical tubing
Stainless and head-resisting pipe, pressure tubing, and mechanical tubing
Aircraft tubing
Pipe

Source: Ref 6

Some of the quality descriptors listed in Table 8 such as forging quality or cold extrusion quality are self-explanatory. The meaning of others is less obvious: for example, merchant quality hot-rolled carbon steel bars are made for noncritical applications requiring modest strength and mild bending or forming, but not requiring forging or heat treating. The descriptor for one particular steel commodity is not necessarily carried over to subsequent products made from that commodity--for example, standard quality cold-finished bars are made from special quality hot-rolled bars.

The various mechanical and physical attributes implied by a quality descriptor arise from the combined effects of several factors, including:

- The degree of internal soundness
- The relative uniformity of chemical composition
- The relative freedom from surface imperfections
- The size of the discard cropped from the ingot
- Extensive testing during manufacture
- The number, size, and distribution of nonmetallic inclusions
- Hardenability requirements

Control of these factors during manufacture is necessary to achieve mill products having the desired characteristics. The extent of the control over these and other related factors is another piece of information conveyed by the quality descriptor.

Some, but not all, of the fundamental descriptors may be modified by one or more additional requirements, as may be appropriate: special discard, macroetch test, restricted chemical composition, maximum incidental (residual) alloy, special hardenability or austenitic grain size. These restrictions could be applied to forging quality alloy steel bars, but not to merchant quality bars.

Understanding the various quality descriptors is complicated by the fact that most of the requirements that qualify a steel for a particular descriptor are subjective. Only nonmetallic inclusion count, restrictions on chemical composition ranges and incidental alloying elements, austenitic grain size, and special hardenability are quantified. The subjective evaluation of the other characteristics depends on the skill and experience of those who make the evaluation. Although the use of these subjective quality descriptors might seem imprecise and unworkable, steel products made to meet the requirements of a particular quality descriptor can be relied upon to have those characteristics necessary for that product to be used in the indicated application or fabrication operation.

Effects of Alloying Elements (Ref 6)

Steels form one of the most complex group of alloys in common use. The synergistic effect of alloying elements and heat treatment produce a tremendous variety of microstructures and properties (characteristics). Given the limited scope of this article, it would be impossible to include a detailed survey of the effects of alloying elements on the iron-carbon equilibrium diagram. This complicated subject, which is briefly reviewed in the article "Microstructures, Processing, and Properties of Steels" in this Volume, lies in the domain of ferrous physical metallurgy and has also been reviewed extensively in the literature (Ref 7, 8, 9, 10, 11). In this section, the effects of various elements on steelmaking (deoxidation) practices and steel characteristics will be briefly outlined. It should be noted that the effects of a single alloying elements are modified by the influence of other elements. These interrelations must be considered when evaluating a change in the composition of a steel. For the sake of simplicity, however, the various alloying elements listed below are discussed separately.

Carbon. The amount of carbon required in the finished steel limits the type of steel that can be made. As the carbon content of rimmed steels increases, surface quality becomes impaired. Killed steels in approximately the 0.15 to 0.30% C content level may have poorer surface quality and require special processing to attain surface quality comparable to steels with higher or lower carbon contents. Carbon has a moderate tendency to segregate, and carbon segregation is often more significant than the segregation of other elements. Carbon, which has a major effect on steel properties, is the principal hardening element in all steel. Tensile strength in the as-rolled condition increases as carbon content increases (up to about 0.85% C). Ductility and weldability decrease with increasing carbon.

Manganese has less of a tendency toward macrosegregation than any of the common elements. Steels above 0.60% Mn cannot be readily rimmed. Manganese is beneficial to surface quality in all carbon ranges (with the exception of extremely low carbon rimmed steels) and is particularly beneficial in resulfurized steels. It contributes to strength and

hardness, but to a lesser degree than does carbon; the amount of increase is dependent upon the carbon content. Increasing the manganese content decreases ductility and weldability, but to a lesser extent than does carbon. Manganese has a strong effect on increasing the hardenability of a steel.

Phosphorus segregates, but to a lesser degree than carbon and sulfur. Increasing phosphorus increases strength and hardness and decreases ductility and notch impact toughness in the as-rolled condition. The decreases in ductility and toughness are greater in quenched and tempered higher-carbon steels. Higher phosphorus is often specified in low-carbon free-machining steels to improve machinability (see the article "Machinability of Steels" in this Volume).

Sulfur. Increased sulfur content lowers transverse ductility and notch impact toughness but has only a slight effect on longitudinal mechanical properties. Weldability decreases with increasing sulfur content. This element is very detrimental to surface quality, particularly in the lower-carbon and lower-manganese steels. For these reasons, only a maximum limit is specified for most steels. The only exception is the group of free-machining steels, where sulfur is added to improve machinability; in this case a range is specified (see the article "Machinability of Steels" in this Volume). Sulfur has a greater segregation tendency than any of the other common elements. Sulfur occurs in steel principally in the form of sulfide inclusions. Obviously, a greater frequency of such inclusions can be expected in the resulfurized grades.

Silicon is one of the principal deoxidizers used in steelmaking; therefore, the amount of silicon present is related to the type of steel. Rimmed and capped steels contain no significant amounts of silicon. Semikilled steels may contain moderate amounts of silicon, although there is a definite maximum amount that can be tolerated in such steels. Killed carbon steels may contain any amount of silicon up to 0.60% maximum.

Silicon is somewhat less effective than manganese in increasing as-rolled strength and hardness. Silicon has only a slight tendency to segregate. In low-carbon steels, silicon is usually detrimental to surface quality, and this condition is more pronounced in low-carbon resulfurized grades.

Copper has a moderate tendency to segregate. Copper in appreciable amounts is detrimental to hot-working operations. Copper adversely affects forge welding, but it does not seriously affect arc or oxyacetylene welding. Copper is detrimental to surface quality and exaggerates the surface defects inherent in resulfurized steels. Copper is, however, beneficial to atmospheric corrosion resistance when present in amounts exceeding 0.20%. Steels containing these levels of copper are referred to as weathering steels and are described in the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume; they are also included in the descriptions of high-strength low-alloy steels given later in this article.

Lead is sometimes added to carbon and alloy steels through mechanical dispersion during teeming for the purpose of improving the machining characteristics of the steels. These additions are generally in the range of 0.15 to 0.35% (see the article "Machinability of Steels" in this Volume for details).

Boron is added to fully killed steel to improve hardenability. Boron-treated steels are produced to a range of 0.0005 to 0.003%. Whenever boron is substituted in part for other alloys, it should be done only with hardenability in mind because the lowered alloy content may be harmful for some applications. Boron is most effective in lower carbon steels. Boron steels are discussed in the Section "Hardenability of Carbon and Low-Alloy Steels" in this Volume.

Chromium is generally added to steel to increase resistance to corrosion and oxidation, to increase hardenability, to improve high-temperature strength, or to improve abrasion resistance in high-carbon compositions. Chromium is a strong carbide former. Complex chromium-iron carbides go into solution in austenite slowly; therefore, a sufficient heating time before quenching is necessary.

Chromium can be used as a hardening element, and is frequently used with a toughening element such as nickel to produce superior mechanical properties. At higher temperatures, chromium contributes increased strength; it is ordinarily used for applications of this nature in conjunction with molybdenum.

Nickel, when used as an alloying element in constructional steels, is a ferrite strengthener. Because nickel does not form any carbide compounds in steel, it remains in solution in the ferrite, thus strengthening and toughening the ferrite phase. Nickel steels are easily heat treated because nickel lowers the critical cooling rate. In combination with chromium, nickel produces alloy steels with greater hardenability, higher impact strength, and greater fatigue resistance than can be achieved in carbon steels.

Molybdenum is added to constructional steels in the normal amounts of 0.10 to 1.00%. When molybdenum is in solid solution in austenite prior to quenching, the reaction rates for transformation become considerably slower as compared with carbon steel. Molybdenum can induce secondary hardening during the tempering of quenched steels and enhances the creep strength of low-alloy steels at elevated temperatures. Alloy steels that contain 0.15 to 0.30% Mo display a minimized susceptibility to temper embrittlement (see the article "Embrittlement of Steels" in this Volume for a discussion of temper embrittlement and other forms of thermal embrittlement).

Niobium. Small additions of niobium increase the yield strength and, to a lesser degree, the tensile strength of carbon steel. The addition of 0.02% Nb can increase the yield strength of medium-carbon steel by 70 to 100 MPa (10 to 15 ksi). This increased strength may be accompanied by considerably impaired notch toughness unless special measures are used to refine grain size during hot rolling. Grain refinement during hot rolling involves special thermomechanical processing techniques such as controlled rolling practices, low finishing temperatures for final reduction passes, and accelerated cooling after rolling is completed (further discussion of controlled rolling can be found in the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume).

Aluminum is widely used as a deoxidizer and for control of grain size. When added to steel in specified amounts, it controls austenite grain growth in reheated steels. Of all the alloying elements, aluminum is the most effective in controlling grain growth prior to quenching. Titanium, zirconium, and vanadium are also effective grain growth inhibitors; however, for structural grades that are heat treated (quenched and tempered), these three elements may have adverse effects on hardenability because their carbides are quite stable and difficult to dissolve in austenite prior to quenching.

Titanium and Zirconium. The effects of titanium are similar to those of vanadium and niobium, but it is only useful in fully killed (aluminum-deoxidized) steels because of its strong deoxidizing effects.

Zirconium can also be added to killed high-strength low-alloy steels to obtain improvements in inclusion characteristics, particularly sulfide inclusions where changes in inclusion shape improve ductility in transverse bending.

Carbon Steels

The American Iron and Steel Institute defines carbon steel as follows (Ref 2, 3):

Steel is considered to be carbon steel when no minimum content is specified or required for chromium, cobalt, columbium [niobium], molybdenum, nickel, titanium, tungsten, vanadium or zirconium, or any other element to be added to obtain a desired alloying effect; when the specified minimum for copper does not exceed 0.40 per cent; or when the maximum content specified for any of the following elements does not exceed the percentages noted: manganese 1.65, silicon 0.60, copper 0.60.

Carbon steel can be classified, according to various deoxidation practices, as rimmed, capped, semikilled, or killed steel. Deoxidation practice and the steelmaking process will have an effect on the characteristics and properties of the steel (see

the article "Steel Processing Technology" in this Volume). However, variations in carbon have the greatest effect on mechanical properties, with increasing carbon content leading to increase hardness and strength (see the article "Microstructures, Processing, and Properties of Steels" in this Volume). As such, carbon steels are generally categorized according to their carbon content. Generally speaking, carbon steels contain up to 2% total alloying elements and can be subdivided into low-carbon steels, medium-carbon steels, high-carbon steels, and ultrahigh-carbon steels; each of these designations is discussed below.

As a group, carbon steels are by far the most frequently used steel. Tables 9 and 10 indicate that more than 85% of the steel produced and shipped in the United States is carbon steel. Chemical compositions for carbon steels are provided in the tables referenced in the section "SAE-AISI Designations" in this article. See Tables 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, and 22.

- (a) Effective 1 January 1988, these products are no longer classified as steel mill products by AISI. Consequently, comparable shipment tonnage is now included in applicable semifinished forms or drawn wire.
- (b) Prior to 1988 included in sheets hot rolled.
- (c) Prior to 1988 included in structural pipe and tubing.

Source: Ref 1

- (a) When silicon ranges or limits are required for bar and semifinished products, the values in Table 1 apply. For rods, the following ranges are commonly used: 0.10 max; 0.07-0.15%; 0.10-0.20%; 0.15-0.35%; 0.20-0.40%; and 0.30-0.60%. Steels listed in this table can be produced with additions of lead or boron. Lead steels typically contain 0.15-0.35% Pb and are identified by inserting the letter L in the designation (10L45); boron steels can be expected to contain 0.0005-0.003% B and are identified by inserting the letter B in the designation (10B46).

- (a) When silicon ranges or limits are required, the values shown in Table 2 apply.

Table 19 Low-alloy steel compositions applicable to billets, blooms, slabs, and hot-rolled and cold-finished bars

Slightly wider ranges of compositions apply to plates. The article "Carbon and Low-Alloy Steel Plate" in this volume lists SAE-AISI plate compositions

Source: Ref 16

(a) Small quantities of certain elements that are not specified or required may be found in alloy steels. These elements are to be considered as incidental and are acceptable to the following maximum amount: copper to 0.35%, nickel to 0.25%, chromium to 0.20%, and molybdenum to 0.06%.

(b) Electric furnace steel.

(c) Boron content is 0.0005-0.003%.

- (a) Some PS steels may be supplied to a hardenability requirement.
- (b) Supplied to a hardenability requirement of 15 HRC points within the range of 23-43 HRC at J4 ($\frac{4}{16}$ in. distance from quenched end), subject to agreement between producer and user.
- (c) PS 66 a vanadium content of 0.10-0.15%.

Source: Ref 18

- (a) Maximum contents of sulfur and silicon for all grades: 0.050% S, 0.90% Si.
- (b) Second and third digits of designation indicate minimum yield strength in ksi. Suffix X indicates that the steel contains niobium, vanadium, nitrogen, or other alloying elements. A second suffix K indicates that the steel is produced fully killed using fine-grain practice; otherwise, the steel is produced semikilled.

(a) These grades remain standard for wire rods.

(b) Limits apply to semifinished products for forgings, bars, wire rods, and seamless tubing.

(c) Boron content 0.0005-0.003%.

(d) Contains 12.00-15.00% W.

(e) Contains 15.00-18.00% W.

(f) Contains 1.50-2.00% W.

Low-carbon steels contain up to 0.30% C. The largest category of this class of steel is flat-rolled products (sheet or strip) usually in the cold-rolled and annealed condition. The carbon content for these high-formability steels is very low, less than 0.10% C, with up to 0.4% Mn. Typical uses are in automobile body panels, tin plate, and wire products.

For rolled steel structural plates and sections, the carbon content may be increased to approximately 0.30%, with higher manganese up to 1.5%. These latter materials may be used for stampings, forgings, seamless tubes, and boiler plate.

Medium-carbon steels are similar to low-carbon steels except that the carbon ranges from 0.30 to 0.60% and the manganese from 0.60 to 1.65%. Increasing the carbon content to approximately 0.5% with an accompanying increase in manganese allows medium-carbon steels to be used in the quenched and tempered condition. The uses of medium carbon-manganese steels include shafts, couplings, crankshafts, axles, gears, and forgings. Steels in the 0.40 to 0.60% C range are also used for rails, railway wheels, and rail axles.

High-carbon steels contain from 0.60 to 1.00% C with manganese contents ranging from 0.30 to 0.90%. High-carbon steels are used for spring materials and high-strength wires.

Ultrahigh-carbon steels are experimental alloys containing approximately 1.25 to 2.0% C. These steels are thermomechanically processed to produce microstructures that consist of ultrafine, equiaxed grains of ferrite and a uniform distribution of fine, spherical, discontinuous proeutectoid carbide particles (Ref 13). Such microstructures in these steels have led to superplastic behavior (Ref 14). Properties of these experimental steels are described in *Forming and Forging*, Volume 14 of *ASM Handbook*, formerly 9th Edition *Metals Handbook* (see the Appendix to the article "Superplastic Sheet Forming," entitled "Superplasticity in Iron-Base Alloys").

High-Strength Low-Alloy Steels

High-strength low-alloy (HSLA) steels, or microalloyed steels, are designed to provide better mechanical properties and/or greater resistance to atmospheric corrosion than conventional carbon steels. They are not considered to be alloy steels in the normal sense because they are designed to meet specific mechanical properties rather than a chemical composition (HSLA steels have yield strengths of more than 275 MPa, or 40 ksi). The chemical composition of a specific HSLA steel may vary for different product thickness to meet mechanical property requirements. The HSLA steels have low carbon contents (0.50 to ~0.25% C) in order to produce adequate formability and weldability, and they have manganese contents up to 2.0%. Small quantities of chromium, nickel, molybdenum, copper, nitrogen, vanadium, niobium, titanium, and zirconium are used in various combinations.

The HSLA steels are commonly furnished in the as-rolled condition. They may also be supplied in a controlled-rolled, normalized, or precipitation-hardened condition to meet specific property requirements. Primary applications for HSLA steels include oil and gas line pipe, ships, offshore structures, automobiles, off-highway equipment, and pressure vessels.

HSLA Classification. The types of HSLA steels commonly used include (Ref 15):

- *Weathering steels*, designed to exhibit superior atmospheric corrosion resistance
- *Control-rolled steels*, hot rolled according to a predetermined rolling schedule designed to develop a highly deformed austenite structure that will transform to a very fine equiaxed ferrite structure on cooling
- *Pearlite-reduced steels*, strengthened by very fine-grain ferrite and precipitation hardening but with low carbon content and therefore little or no pearlite in the microstructure
- *Microalloyed steels*, with very small additions (generally <0.10% each) of such elements as niobium, vanadium, and/or titanium for refinement of grain size and/or precipitation hardening
- *Acicular ferrite steel*, very low carbon steels with sufficient hardenability to transform on cooling to a very fine high-strength acicular ferrite (low-carbon bainite) structure rather than the usual polygonal ferrite structure
- *Dual-phase steels*, processed to a micro-structure of ferrite containing small uniformly distributed regions of high-carbon martensite, resulting in a product with low yield strength and a high rate of work hardening, thus providing a high-strength steel of superior formability

The various types of HSLA steels may also have small additions of calcium, rare-earth elements, or zirconium for sulfide inclusion shape control. Compositions, properties, and applications of these steels can be found in the articles "High-Strength Structural and High-Strength Low-Alloy Steels," "Dual-Phase Steels," and "High-Strength Low-Alloy Steel Forgings" in this Volume.

Low-Alloy Steels

Low-alloy steels constitute a category of ferrous materials that exhibit mechanical properties superior to plain carbon steels as the result of additions of such alloying elements as nickel, chromium, and molybdenum. Total alloy content can

range from 2.07% up to levels just below that of stainless steels, which contain a minimum of 10% Cr. For many low-alloy steels, the primary function of the alloying elements is to increase hardenability in order to optimize mechanical properties and toughness after heat treatment. In some cases, however, alloy additions are used to reduce environmental degradation under certain specified service conditions.

As with steels in general, low-alloy steels can be classified according to:

- *Chemical composition*, such as nickel steels, nickel-chromium steels, molybdenum steels, chromium-molybdenum steels, and so on, as described in the section "SAE-AISI Designations" in this article and as shown in Table 11
- *Heat treatment*, such as quenched and tempered, normalized and tempered, annealed, and so on
- *Weldability*, as described in the article "Weldability of Steels" in this Volume

Because of the wide variety of chemical compositions possible and the fact that some steels are used in more than one heat-treated condition, some overlap exists among the alloy steel classifications. In this article, four major groups of alloy steels are addressed: (1) low-carbon quenched and tempered (QT) steels, (2) medium-carbon ultrahigh-strength steels, (3) bearing steels, and (4) heat-resistant chromium-molybdenum steels.

Low-carbon quenched and tempered steels combine high yield strength (from 350 to 1035 MPa, or 50 to 150 ksi) and high tensile strength with good notch toughness, ductility, corrosion resistance, or weldability. The various steels have different combinations of these characteristics based on their intended applications. The chemical compositions of typical QT low-carbon steels are given in Table 23. Many of the steels are covered by ASTM specifications. However, a few steels, such as HY-80 and HY-100, are covered by military specifications. The steels listed are used primarily as plate. Some of these steels, as well as other similar steels, are produced as forgings or castings. More detailed information on low-carbon QT steels can be found in the articles "Hardenable Carbon and Low-Alloy Steels" and "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume.

Table 23 Chemical compositions for typical low-alloy steels

(a) Single values represent the maximum allowable.

(b) Zirconium may be replaced by cerium. When cerium is added, the cerium/sulfur ratio should be approximately 1.5/1, based on heat analysis.

Medium-carbon ultrahigh-strength steels are structural steels with yield strengths that can exceed 1380 MPa (200 ksi). Table 23 lists typical compositions. Many of these steels are covered by SAE-AISI designations or are proprietary compositions. Product forms include billet, bar, rod, forgings, sheet, tubing, and welding wire. A review of the heat treatments and resulting properties of these steels can be found in the article "Ultrahigh-Strength Steels" in this Volume.

Bearing steels used for ball and roller bearing applications are comprised of low-carbon (0.10 to 0.20% C) case-hardened steels and high carbon (~1.0% C) through-hardened steels (Table 23). Many of these steels are covered by SAE-AISI designations. Selection and properties of these materials are discussed in the article "Bearing Steels" in this Volume.

Chromium-molybdenum heat-resistant steels contain 0.5 to 9% Cr and 0.5 to 1.0% Mo. The carbon content is usually below 0.20%. The chromium provides improved oxidation and corrosion resistance, and the molybdenum increases strength at elevated temperatures. They are generally supplied in the normalized and tempered, quenched and tempered, or annealed condition. Chromium-molybdenum steels are widely used in the oil and gas industries and in fossil fuel and nuclear power plants. Various product forms and corresponding ASTM specifications for these steels are given in Table 24. Nominal chemical compositions are provided in Table 25. High-temperature property data for chromium-molybdenum steels are reviewed extensively in the article "Elevated-Temperature Properties of Ferritic Steels" in this Volume.

Designations for Steels

A designation is the specific identification of each grade, type, or class of steel by a number, letter, symbol, name, or suitable combination thereof unique to a particular steel. Grade, type, and class are terms used to classify steel products. Within the steel industry, they have very specific uses: grade is used to denote chemical composition; type is used to indicate deoxidation practice; and class is used to describe some other attribute, such as strength level or surface smoothness.

In ASTM specifications, however, these terms are used somewhat interchangeably. In ASTM A 533, for example, type denotes chemical composition, while class indicates strength level. In ASTM A 515, grade identifies strength level; the maximum carbon content permitted by this specification depends on both plate thickness and strength level. In ASTM A 302, grade denotes requirements for both chemical composition and mechanical properties. ASTM A 514 and A 517 are specifications for high-strength quenched and tempered plate for structural and pressure vessel applications, respectively; each contains several compositions that can provide the required mechanical properties. However, A 514 type A has the identical composition limits as A 517 grade. Additional information can be found in the section "ASTM (ASME) Specifications" in this article.

Chemical composition is by far the most widely used basis for classification and/or designation of steels. The most commonly used system of designation in the United States is that of the Society of Automotive Engineers (SAE) and the American Iron and Steel Institute (AISI). The Unified Numbering System (UNS) is also being used with increasing frequency. Each of these designation systems is described below.

SAE-AISI Designations

As stated above, the most widely used system for designating carbon and alloy steels is the SAE-AISI system. As a point of technicality, there are two separate systems, but they are nearly identical and have been carefully coordinated by the two groups. It should be noted, however, that AISI has discontinued the practice of designating steels. Therefore, the reader should consult Volume 1, *Materials*, of the *SAE Handbook* for the most up-to-date information.

The SAE-AISI system is applied to semi-finished forgings, hot-rolled and cold-finished bars, wire rod and seamless tubular goods, structural shapes, plates, sheet, strip, and welded tubing. Table 11 summarizes the numerical designations used in both SAE and AISI.

Carbon steels contain less than 1.65% Mn, 0.60% Si, and 0.60% Cu; they comprise the 1xxx groups in the SAE-AISI system and are subdivided into four distinct series as a result of the difference in certain fundamental properties among them. Plain carbon steels in the 10xx group are listed in Tables 12 and 13; note that ranges and limits of chemical composition depend on the product form. Designations for merchant quality steels, given in Table 14, include the prefix M. A carbon steel designation with the letter B inserted between the second and third digits indicates the steel contains 0.0005 to 0.003% B. Likewise, the letter L inserted between the second and third digits indicates that the steel contains 0.15 to 0.35% Pb for enhanced machinability. Resulfurized carbon steels in the 11xx group are listed in Table 15, and resulfurized and rephosphorized carbon steels in the 12xx group are listed in Table 16. Both of these groups of steels are produced for applications requiring good machinability. Tables 17 and 18 list steels having nominal manganese contents of between 0.9 and 1.5% but no other alloying additions; these steels now have 15xx designations in place of the 10xx designations formerly used.

Certain steels have hardenability requirements in addition to the limits and ranges of chemical composition. They are distinguished from similar grades that have no hardenability requirement by the use of the suffix H. Limits and ranges of chemical composition for all carbon steel products reflect the restrictions on heat and product analyses given in Tables 1, 2, and 5. Hardenability characteristics of carbon steels and the carbon and carbon-boron H steels are discussed in the

article "Hardenable Carbon and Low-Alloy Steels" in this Volume. Corresponding hardenability bands for these steels are given in the article "Hardenability Curves". Except where indicated, all of these designations for carbon steels are both AISI and SAE designations.

Alloy steels contain manganese, silicon, or copper in quantities greater than those listed for the carbon steels, or they have specified ranges or minimums for one or more of the other alloying elements. In the AISI-SAE system of designations, the major alloying elements in a steel are indicated by the first two digits of the designation (Table 11). The amount of carbon, in hundredths of a percent, is indicated by the last two (or three) digits. The chemical compositions of AISI-SAE standard grades of alloy steels are given in Table 19. For alloy steels that have specific hardenability requirements, the suffix H is used to distinguish these steels from corresponding grades that have no hardenability requirement (see the article "Hardenable Carbon and Low-Alloy Steels" in this Volume for chemical compositions of alloy H steels). As with carbon steels, the letter B inserted between the second and third digits indicates that the steel contains boron. The prefix E signifies that the steel was produced by the electric furnace process. Limits and ranges of chemical composition for all alloy steel products reflect the restrictions on heat and product analyses given in Tables 1 through 7. The designations in Table 19 are both AISI and SAE designations unless otherwise indicated.

Potential standard steels are listed in SAE J1081 and Table 20. These are experimental grades to which no regular AISI-SAE designations have been assigned. Some were developed to minimize the nickel content; others were devised to improve a particular attribute of a standard grade of alloy steel.

HSLA Steels. Several grades of HSLA steel are described in SAE Recommended Practice J410; their chemical compositions and minimum mechanical properties are listed in Table 21. These steels have been developed as a compromise between the convenient fabrication characteristics and low cost of plain carbon steels and the high strength of heat-treated alloy steels. These steels have excellent strength and ductility as-rolled.

Formerly Listed SAE Steels. A number of grades of carbon and alloy steels have been deleted from the list of SAE standard steels due to lack of use. For the convenience of those who might encounter an application for one of these grades, they are listed in Table 22.

UNS Designations

The Unified Numbering System (UNS) has been developed by ASTM and SAE and several other technical societies, trade associations, and United States government agencies. A UNS number, which is a designation of chemical composition and not a specification, is assigned to each chemical composition of a metallic alloy. Available UNS designation are included in the tables in this article.

The UNS designation of an alloy consists of a letter and five numerals. The letters indicate the broad class of alloys; the numerals define specific alloys within that class. Existing designation systems, such as the AISI-SAE system for steels, have been incorporated into UNS designations. UNS is described in greater detail in SAE J1086 and ASTM E 527.

AMS Designations

Aerospace Materials Specifications (AMS), published by SAE, are complete specifications that are generally adequate for procurement purposes. Most of the AMS designations pertain to materials intended for aerospace applications; the specifications may include mechanical property requirements significantly more severe than those for grades of steel having similar compositions but intended for other applications. Processing requirements, such as for consumable electrode remelting, are common in AMS steels. Chemical compositions for AMS grades of carbon and alloy steels are given in Tables 26 and 27, respectively.

Table 26 Product descriptions and carbon contents for wrought carbon steels (AMS designations)

(b) MAM, metric aerospace material specifications

Specifications for Steels

A specification is a written statement of the requirements, both technical and commercial, that a product must meet; it is a document that controls procurement. There are nearly as many formats for specifications as there are groups writing them, but any reasonably adequate specification will provide information about the items listed below:

- *Scope* may cover product classification, including size range when necessary, condition, and any comments on product processing deemed helpful to either the supplier or user. An information title plus a statement of the required form may be used instead of a scope clause
- *Chemical composition* may be detailed, or it may be indicated by a well-recognized designation based on chemical composition. The SAE-AISI designations are frequently used
- *The quality statement* includes any appropriate quality descriptor and whatever additional requirements might be necessary. It may also include the type of steel and the steelmaking processes permitted
- *Quantitative requirements* identify allowable ranges of the composition properties and all physical and mechanical properties necessary to characterize the material. Test methods used to determine these properties should also be included, at least by reference to standard test methods. For reasons of economy, this section should be limited to those properties that are germane to the intended application
- *Additional requirements* can include special tolerances, surface preparation, and edge finish on flat-rolled products, as well as special identification, packaging, and loading instructions

Engineering societies, associations, and institutes whose members make, specify, or purchase steel products publish standard specifications, many of which have become well known and highly respected. Some of the important specification-writing groups are listed below. It is obvious from the names of some of these that the specifications prepared by a particular group may be limited to its own specialized field:

Organization	Acronym
--------------	---------

Association of American Railroads	AAR
American Bureau of Shipbuilding	ABS
American Petroleum Institute	API
American Railway Engineering Association	AREA
American Society of Mechanical Engineers	ASME
American Society for Testing and Materials	ASTM
Society of Automotive Engineers	SAE
Aerospace Material Specification (of SAE)	AMS

ASTM (ASME) Specifications

The most widely used standard specifications for steel products in the United States are those published by ASTM. These are complete specifications, generally adequate for procurement purposes. Many ASTM specifications apply to specific products, such as A 574 for alloy steel socket head cap screws. These specifications are generally oriented toward performance of the fabricated end product, with considerable latitude in chemical composition of the steel used to make the end product.

ASTM specifications represent a consensus among producers, specifiers, fabricators, and users of steel mill products. In many cases, the dimensions, tolerances, limits, and restrictions in the ASTM specifications are similar to or the same as the corresponding items of the standard practices in the AISI Steel Products Manuals. Many of the ASTM specifications have been adopted by the American Society of Mechanical Engineers (ASME) with little or no modification; ASME uses the prefix S and the ASTM designation for these specifications. For example, ASME-SA213 and ASTM A 213 are identical.

Steel products can be identified by the number of the ASTM specification to which they are made. The number consists of the letter A (for ferrous materials) and an arbitrary, serially assigned number. Citing the specification number, however, is not always adequate to completely describe a steel product. For example, A 434 is the specification for heat-treated (hardened and tempered) alloy steel bars. To completely describe steel bars indicated by this specification, the grade (SAE-AISI designation in this case) and class (required strength level) must also be indicated. The ASTM specification A 434 also incorporates, by reference, two standards for test methods (A 370 for mechanical testing and E 112 for grain size determination) and A 29, which specifies the general requirements for bar products.

SAE-AISI designations for the compositions of carbon and alloy steels are sometimes incorporated into the ASTM specifications for bars, wires, and billets for forging. Some ASTM specifications for sheet products include SAE-AISI designations for composition. The ASTM specifications for plates and structural shapes generally specify the limits and ranges of chemical composition directly, without the SAE-AISI designations. Table 28 includes a list of some of the ASTM specifications that incorporate AISI-SAE designations for compositions of the different grades of steel.

Table 28 ASTM specifications that incorporate AISI-SAE designations

A 29	Carbon and alloy steel bars, hot rolled and cold finished
------	--

A 108	Standard quality cold-finished carbon steel bars
A 295	High carbon-chromium ball and roller bearing steel
A 304	Alloy steel bars having hardenability requirements
A 322	Hot-rolled alloy steel bars
A 331	Cold-finished alloy steel bars
A 434	Hot-rolled or cold-finished quenched and tempered alloy steel bars
A 505	Hot-rolled and cold-rolled alloy steel sheet and strip
A 506	Regular quality hot-rolled and cold-rolled alloy steel sheet and strip
A 507	Drawing quality hot-rolled and cold-rolled alloy steel sheet and strip
A 510	Carbon steel wire rods and coarse round wire
A 534	Carburizing steels for antifriction bearings
A 535	Special quality ball and roller bearing steel
A 544	Scrapless nut quality carbon steel wire
A 545	Cold-heading quality carbon steel wire for machine screws
A 546	Cold-heading quality medium high carbon steel wire for hexagon-head bolts
A 547	Cold-heading quality alloy steel wire for hexagon-head bolts
A 548	Cold-heading quality carbon steel wire for tapping or sheet metal screws
A 549	Cold-heading quality carbon steel wire for wood screws
A 575	Merchant quality hot-rolled carbon steel bars
A 576	Special quality hot-rolled carbon steel bars
A 646	Premium quality alloy steel blooms and billets for aircraft and aerospace forgings

A 659	Commercial quality hot-rolled carbon steel sheet and strip
A 682	Cold-rolled spring quality carbon steel strip, generic
A 684	Untempered cold-rolled high-carbon steel strip
A 689	Carbon and alloy steel bars for springs
A 711	Carbon and alloy steel blooms, billets, and slabs for forging
A 713	High-carbon spring steel wire for heat-treated components
A 752	Alloy steel wire rods and coarse around wire
A 827	Carbon steel plates for forging and similar applications
A 829	Structural quality alloy steel plates
A 830	Structural quality carbon steel plates

General Specifications. Several ASTM specifications, such as A 20 covering steel plate used for pressure vessels, contain the general requirements common to each member of a broad family of steel products. Table 29 lists general specifications for a number of product forms. As shown in Table 29, these general specifications are often supplemented by additional specifications describing a different mill form or intermediate fabricated product. Articles describing the compositions and properties of steels used for each of the product forms listed in Table 29 follow in this Section.

Table 29 General ASTM specifications (in boldface) with corresponding supplementary specifications used to describe primary carbon and low-alloy steel product forms

ASTM designation	Title of specification
ASTM A 6/A 6M: General requirements for rolled steel plates, shapes, sheet piling, and bars for structural use ^(a)	
A 36/A 36M	Structural steel
A 131/A 131M	Structural steel for ships
A 242/A 242M	High-strength low-alloy structural steel
A 283/A 283M	Low and intermediate tensile strength carbon steel plates, shapes, and bars

A 284/A 284M	Low and intermediate tensile strength carbon-silicon steel plates for machine parts and general construction
A 328/A 328M	Steel sheet piling
A 441/A 441M	High-strength low-alloy structural manganese-vanadium steel
A 514/A 514M	High yield strength, quenched and tempered alloy steel plate suitable for welding
A 529/A 529M	Structural steel with 290 MPa (42 ksi) minimum yield point (12.7 mm, or $\frac{1}{2}$ in., maximum thickness)
A 572/A 572M	High-strength low-alloy niobium-vanadium steels of structural quality
A 573/A 573M	Structural carbon steel plates of improved toughness
A 588/A 588M	High-strength low-alloy structural steel with 345 MPa (50 ksi) minimum yield point to 100 mm (4 in.) thick
A 633/A 633M	Normalized high-strength low-alloy structural steel
A 656/A 656M	Hot-rolled structural steel, high-strength low-alloy plate with improved formability
A 678/A 678M	Quenched and tempered carbon steel plates for structural applications
A 690/A 690M	High-strength low-alloy steel H-piles and sheet piling for use in marine environments
A 709	Structural steel for bridges
A 710/A 710M	Low-carbon age-hardening nickel-copper-chromium-molybdenum-niobium and nickel-copper-niobium alloy steels
A 769/A 769M	Electric resistance welded steel shapes
A 786/A 786M	Rolled steel floor plates
A 808/A 808M	High-strength low-alloy carbon-manganese-niobium-vanadium steel of structural quality with improved notch toughness
A 827	Plates, carbon steel, for forging and similar applications
A 829	Plates, alloy steel, structural quality
A 830	Plates, carbon steel, structural quality, furnished to chemical composition requirements

A 852/A 852M	Quenched and tempered low-alloy structural steel plate
A 857	Steel sheet piling, cold formed, light gage
A 871/A 871M	High-strength low-alloy structural steel plate with atmospheric corrosion resistance
ASTM A 20/A 20M: General requirements for steel plates for pressure vessels ^(a)	
A 202/A 202M	Pressure vessel plates, alloy steel, chromium-manganese-silicon
A 203/A 203M	Pressure vessel plates, alloy steel, nickel
A 204/A 204M	Pressure vessel plates, alloy steel, molybdenum
A 225/A 225M	Pressure vessel plates, alloy steel, manganese-vanadium
A 285/A 285M	Pressure vessel plates, carbon steel, low and intermediate tensile strength
A 299/A 299M	Pressure vessel plates, carbon steel, manganese-silicon
A 302/A 302M	Pressure vessel plates, alloy steel, manganese-molybdenum and manganese-molybdenum-nickel
A 353/A 353M	Pressure vessel plates, alloy steel, 9% Ni, double normalized and tempered
A 387/A 387M	Pressure vessel plates, alloy steel, chromium-molybdenum
A 442/A 442M	Pressure vessel plates, carbon steel, improved transition properties
A 455/A 455M	Pressure vessel plates, carbon steel, high-strength manganese
A 515/A 515M	Pressure vessel plates, carbon steel, for intermediate- and higher-temperature service
A 516/A 516M	Pressure vessel plates, carbon steel, for moderate- and lower-temperature service
A 517/A 517M	Pressure vessel plates, alloy steel, high-strength, quenched and tempered
A 533/A 533M	Pressure vessel plates, alloy steel, quenched and tempered manganese-molybdenum and manganese-molybdenum-nickel
A 537/A 537M	Pressure vessel plates, heat-treated carbon-manganese-silicon steel

A 538/A 538M	Pressure vessel plates, alloy steel, precipitation hardening (maraging), 18% Ni
A 542/A 542M	Pressure vessel plates, alloy steel, quenched and tempered chromium-molybdenum
A 543/A 543M	Pressure vessel plates, alloy steel, quenched and tempered nickel-chromium-molybdenum
A 553/A 553M	Pressure vessel plates, alloy steel, quenched and tempered 8 and 9% Ni
A 562/A 562M	Pressure vessel plates, carbon steel, manganese, titanium, for glass or diffused metallic coatings
A 605/A 605M	Pressure vessel plates, alloy steel, quenched and tempered nickel-cobalt-molybdenum-chromium
A 612/A 612M	Pressure vessel plates, carbon steel, high strength, for moderate- and lower-temperature service
A 645/A 645M	Pressure vessel plates, 5% Ni, alloy steel, specially heat treated
A 662/A 662M	Pressure vessel plates, carbon-manganese, for moderate- and lower-temperature service
A 724/A 724M	Pressure vessel plates, carbon steel, quenched and tempered, for welded layered pressure vessels
A 734/A 734M	Pressure vessel plates, alloy steel and high-strength low-alloy steel, quenched and tempered
A 735/A 735M	Pressure vessel plates, low-carbon manganese-molybdenum-niobium alloy steel, for moderate- and lower-temperature service
A 736/A 736M	Pressure vessel plates, low-carbon age-hardening nickel-copper-chromium-molybdenum-niobium alloy steel
A 737/A 737M	Pressure vessel plates, high-strength low-alloy steel
A 738/A 738M	Pressure vessel plates, heat-treated carbon-manganese-silicon steel, for moderate- and lower-temperature service
A 782/A 782M	Pressure vessel plates, quenched and tempered manganese-chromium-molybdenum-silicon-zirconium alloy steel
A 832/A 832M	Pressure vessel plates, alloy steel, chromium-molybdenum-vanadium-titanium-boron
A 841/A 841M	Pressure vessel plates, produced by the thermomechanical control process
A 844/A 844M	Pressure vessel plates 9% Ni alloy, produced by the direct-quenching process
ASTM A29/A 29M: ^(b) : General requirements for hot-rolled and cold-finished carbon and alloy steel bars ^(c)	

<i>Hot-rolled carbon steel bars</i>	
A 321	Steel bars, carbon, quenched and tempered
A 499	Steel bars and shapes rerolled from rail steel, hot-rolled carbon
A 575 ^(b)	Steel bars, merchant quality, hot-wrought carbon
A 576 ^(b)	Steel bars, carbon, hot wrought, special quality
A 663	Steel bars, merchant quality, hot-wrought carbon, subject to mechanical property requirements
A 675	Steel bars and bar-size shapes, carbon, hot wrought, special quality, subject to mechanical property requirements
A 689 ^(b)	Steel bars for springs, carbon and alloy
A 695	Steel bars, carbon, hot wrought, special quality, for fluid power applications
<i>Cold-finished carbon steel bars</i>	
A 108 ^(b)	Steel bars, carbon, cold finished, standard quality
A 311	Steel bars subject to mechanical property requirements, stress relief annealed cold-drawn carbon
<i>Hot-rolled alloy steel bars</i>	
A 322 ^(b)	Steel bars, hot-wrought alloy
A 304 ^(b)	Steel bars, alloy, subject to end-quench hardenability requirements
A 434 ^(b)	Steel bars, alloy, hot wrought or cold finished, quenched and tempered
A 739	Steel bars, alloy, hot wrought, for elevated-temperature or pressure-containing parts, or both
<i>Cold-finished alloy steel bars</i>	
A 331 ^(b)	Steel bars, alloy, cold finished
A 434 ^(b)	Steel bars, alloy, hot rolled or cold finished, quenched and tempered

A 696	Steel bars, carbon, hot rolled and cold finished, special quality, for pressure piping components and other pressure-containing parts
ASTM A 450/A 450M: General requirements for carbon, ferritic-alloy, and austenitic-alloy steel tubes ^(d)	
A 161	Seamless low-carbon and carbon-molybdenum steel still tubes for refinery service
A 178/A 178M	Electric resistance welded carbon steel boiler tubes
A 179/A 179M	Seamless cold-drawn low-carbon steel heat exchanger and condenser tubes
A 192/A 192M	Seamless carbon steel boiler tubes for high-pressure service
A 199/A 199M	Seamless cold-drawn intermediate alloy steel heat exchanger and condenser tubes
A 200	Seamless intermediate alloy steel still tubes for refinery service
A 209/A 209M	Seamless carbon-molybdenum alloy steel boiler and superheater tubes
A 210/A 210M	Seamless medium-carbon steel boiler and superheater tubes
A 213/A 213M	Seamless ferritic and austenitic alloy steel boiler, superheater, and heat exchanger tubes
A 214/A 214M	Electric resistance welded carbon steel heat exchanger and condenser tubes
A 226/A 226M	Electric resistance welded carbon steel boiler and superheater tubes for high-pressure service
A 249/A 249M	Welded austenitic steel, boiler, superheater, heat, exchanger, and condenser tubes
A 250/A 250M	Electric resistance welded carbon-molybdenum alloy steel boiler and superheater tubes
A 268/A 268M	Seamless and welded ferritic stainless steel tubing for general service
A 269	Seamless and welded austenitic stainless steel tubing for general service
A 270	Seamless and welded austenitic stainless steel sanitary tubing
A 271	Seamless austenitic chromium-nickel steel still tubes for refinery service
A 334/A 334M	Seamless and welded carbon and alloy steel tubes for low-temperature service

A 423/A 423M	Seamless and electric welded low-alloy steel tubes
A 539	Electric resistance welded coiled steel tubing for gas and fuel oil lines
A 556/A 556M	Seamless cold-drawn carbon steel feedwater heater tubes
A 557/A 557M	Electric resistance welded carbon steel feedwater heater tubes
A 688/A 688M	Welded austenitic stainless steel feedwater heater tubes
A 692	Seamless medium-strength carbon-molybdenum alloy steel boiler and superheater tubes
A 771	Austenitic stainless steel tubing for breeder reactor core components
A 789/A 789M	Seamless and welded ferritic and austenitic stainless steel tubing for general service
A 791/A 791M	Welded unannealed ferritic stainless steel tubing
A 803/A 803M	Welded ferritic stainless steel feedwater heater tubes
A 822	Seamless, cold-drawn carbon steel piping tubing for hydraulic system service
A 826	Austenitic and ferritic stainless steel duct tubes for breeder reactor core components
A 851	High-frequency induction-welded unannealed austenitic steel condenser tubes
ASTM A 530/A 530M: General requirements for specialized carbon and alloy steel pipe ^(d)	
A 106	Seamless carbon steel pipe for high-temperature service
A 312/A 312M	Seamless and welded austenitic stainless steel pipe
A 333/A 333M	Seamless and welded steel pipe for low-temperature service
A 335/A 335M	Seamless ferritic alloy steel pipe for high-temperature service
A 358/A 358M	Electric fusion welded austenitic chromium-nickel alloy steel pipe for high-temperature service
A 369/A 369M	Carbon and ferritic alloy steel forged and bored pipe for high-temperature service
A 376/A 376M	Seamless austenitic steel pipe for high-temperature central station service

A 381	Metal arc welded steel pipe for high-pressure transmission systems
A 405	Seamless ferritic alloy steel pipe specially heat treated for high-temperature service
A 409/A 409M	Welded large-diameter austenitic steel pipe for corrosive or high-temperature service
A 426	Centrifugally cast ferritic alloy steel pipe for high-temperature service
A 430/A 430M	Austenitic steel forged and bored pipe for high-temperature service
A 451	Centrifugally cast austenitic steel pipe for high-temperature service
A 452	Centrifugally cast austenitic steel cold-wrought pipe for high-temperature service
A 524	Seamless carbon steel pipe for atmospheric and lower temperatures
A 608	Centrifugally cast iron-chromium-nickel high-alloy tubing for pressure application at high temperatures
A 660	Centrifugally cast carbon steel pipe for high-temperature service
A 671	Electric fusion welded steel pipe for atmospheric and lower temperatures
A 672	Electric fusion welded steel pipe for high-pressure service at moderate temperatures
A 691	Carbon and alloy steel pipe electric fusion welded for high-pressure service and high temperatures
A 731/A 731M	Seamless and welded ferritic stainless steel pipe
A 790/A 790M	Seamless and welded ferritic and austenitic stainless steel pipe
A 813/A 813M	Single- or double-welded austenitic stainless steel pipe
A 814/A 814M	Cold-worked welded austenitic stainless steel pipe
A 872	Centrifugally cast ferritic and austenitic stainless steel pipe for corrosive environments
ASTM A 682: General requirements for cold-rolled spring quality high-carbon steel strip ^(e)	
A 680	Steel, carbon strip, cold rolled hard, untempered spring quality
A 684	Steel, carbon strip, cold rolled soft, untempered spring quality

ASTM A 749: General requirements for hot-rolled carbon and high-strength low-alloy steel strip ^(e)	
ASTM A 505 ^(b) : General requirements for hot-rolled and cold-rolled alloy steel sheet and strip ^(e)	
A 506 ^(b)	Alloy steel sheet and strip, hot rolled and cold rolled, regular quality and structural quality
A 507 ^(b)	Alloy steel sheet and strip, hot rolled and cold rolled, drawing quality
A 873/A 873M	Chromium-molybdenum alloy steel sheet and strip for pressure vessels
ASTM A 505 ^(b) : General requirements for carbon steel wire rods and coarse round wire ^(e)	
ASTM A 752 ^(b) : General requirements for alloy steel wire rods and coarse bound wire ^(e)

(e) From *Annual Book of ASTM Standards*, Vol. 01.03.

International Designations and Specifications

The steel industry has undergone major changes during the past 15 to 20 years. No longer is the international steel marketplace dominated by the United States. In fact, the steel produced in all of North America accounts for less than 14% of total world production. The distribution of steel production among various nations is illustrated in Fig. 3; production figures are given in Table 30. With continuing advances in production by third world developing countries (Fig. 4), the international steel marketplace will continue to experience substantial changes during the 1990s.

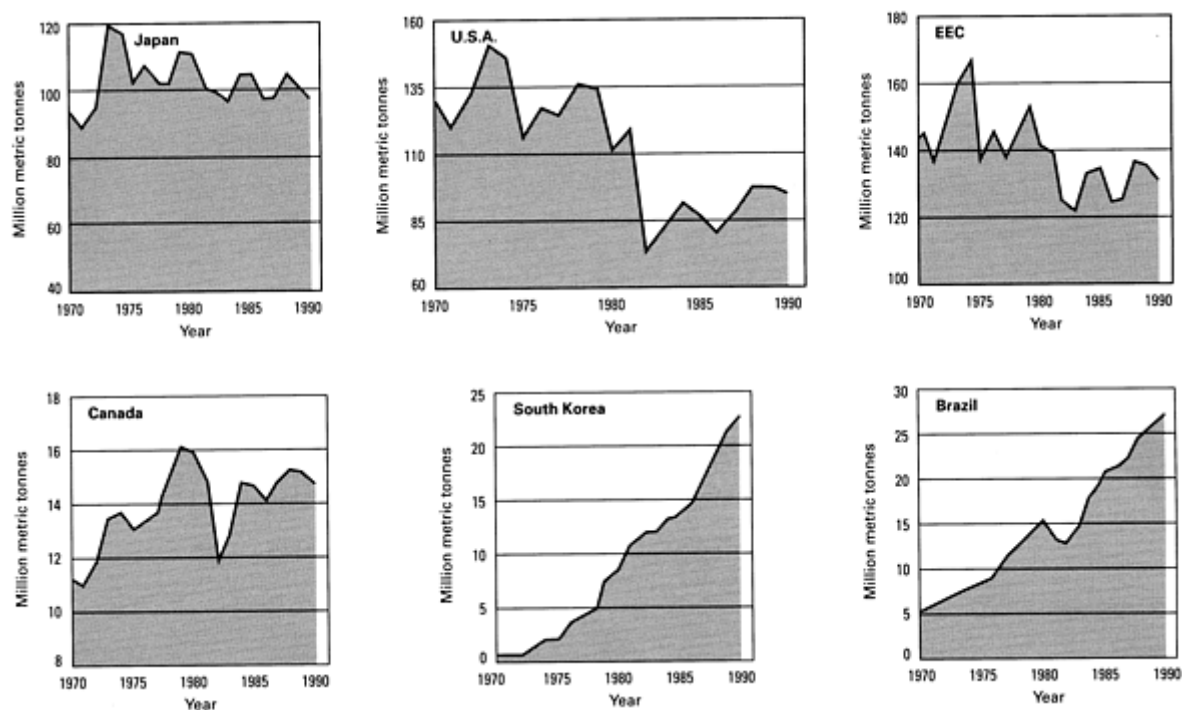

Fig. 4 Annual crude steel production for various industrialized and developing nations. Source: Wharton Econometric Forecasting Associates

Because steelmaking technology is available worldwide, familiarity with international designations and/or specifications for steels is critical. Table 31 cross-references SAE steels with those of a selected group of international designations and specifications, which are described below. Tables 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, and 43 provide chemical compositions for the non-SAE steels listed in Table 31. More detailed information on cross-referencing of steels can be found in Ref 20 and 21.

Table 31 Cross-reference to steels

This table cross-references standard SAE carbon and low-alloy steels to selected chemically similar steels from specifications established by standards organizations from the Federal Republic of Germany, Japan, the United Kingdom, France, Italy, and Sweden. Chemical compositions of the non-SAE steels listed in this table can be found in Tables 32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, and 43.

DIN standards are developed by Deutsches Institut für Normung in the Federal Republic of Germany. All West German steel specifications are preceded by the uppercase letters DIN followed by an alphanumeric or numeric code. The latter method, known as the Werkstoff number, uses numbers only with a decimal point after the first digit. Examples of both methods are given in Tables 31, 32, and 33, which cross-reference SAE and DIN designations and provide chemical compositions for DIN steels.

JIS standards are developed by the Japanese Industrial Standards Committee, which is part of the Ministry of International Trade and Industry in Tokyo. The JIS steel specifications begin with the uppercase letters JIS and are followed by an uppercase letter (G in the case of carbon and low-alloy steels) designating the division (product form) of the standard. This letter is followed by a series of numbers and letters that indicate the specific steel; JIS designations are given in Tables 31, 34, and 35. For example, as indicated in Tables 31 and 34, JIS G3445 STKM11A is a low-carbon tube steel with the following chemical composition:

Element	Percentage/range
Carbon	0.12
Silicon	0.35
Manganese	0.60

Phosphorus	0.040
Sulfur	0.040

British standards (BS) are developed by the British Standards Institute in London, England. Tables 31, 36, and 37 list steels covered by British standards. Similar to the JIS standards, each British designation includes a product form and an alloy code. For example, as indicated in Tables 31 and 37, BS 979 708A37 is a low-alloy steel with the following chemical composition:

Element	Percentage/range
Carbon	0.35-0.40
Silicon	0.10-0.35
Manganese	0.70-1.00
Phosphorus	0.040
Sulfur	0.050
Nickel	...
Chromium	0.90-1.20
Molybdenum	0.15-0.25

AFNOR standards are developed by the Association Francaise de Normalisation in Paris, France. The correct format for reporting AFNOR standards, which are listed in Tables 31, 38, and 39, is as follows. An uppercase NF is placed to the left of the alphanumeric code. This code consists of an uppercase letter followed by a series of digits, which are subsequently followed by an alphanumeric sequence. For example, as indicated in Tables 31 and 38, NF A35-562 35MF6 is a resulfurized (free-cutting) steel with the following composition:

Element	Percentage/range
Carbon	0.33-0.39

Silicon	0.10-0.40
Manganese	1.10-1.70
Phosphorus	0.040
Sulfur	0.09-0.13

UNI standards are developed by the Ente Nazionale Italiano di Unificazione in Milan, Italy. Italian standards are preceded by the uppercase letters UNI followed by a four-digit product form code subsequently followed by an alphanumeric alloy identification (Tables 31, 40, and 41). For example, as indicated in Tables 31 and 40, UNI 5598 3CD5 is a low-carbon steel used for wire rod with the following composition:

Element	Percentage/range
Carbon	0.06
Silicon	...
Manganese	0.25-0.50
Phosphorus	0.035
Sulfur	0.035
Nitrogen	0.007

Swedish standards (SS₁₄) are prepared by the Swedish Standards Institution in Stockholm. Designations begin with the letters SS followed by the number 14 (all Swedish carbon and low-alloy steels are covered by SS₁₄). What subsequently follows is a four-digit numerical sequence similar to the German Werkstoff number. Swedish designations are listed in Tables 31, 42, and 43.

(a) To obtain coefficients in $\mu\text{in./in.} \cdot ^\circ\text{F}$, multiply stated values by 0.556.

(b) Stated value represents average coefficient between 0 °C (32 °F) and indicated temperature.

(c) 10.3 $\mu\text{m/m} \cdot \text{K}$ from -100 to 20 °C (-148 to 68 °F); 9.8 $\mu\text{m/m} \cdot \text{K}$ from -150 to 20 °C (-238 to 68 °F).

(d) Stated value represents average coefficient between 20 and 650 °C (68 and 1200 °F).

(e) Stated value represents average coefficient between 25 °C (75 °F) and indicated temperature.

(f) Stated value represents average coefficient between 20 and 95 °C (68 and 200 °F).

(g) Stated value represents average coefficient between 20 and 370 °C (68 and 700 °F).

(h) 8.6 $\mu\text{m/m} \cdot \text{K}$ from -195 to 20 °C (-320 to 68 °F); 10.0 $\mu\text{m/m} \cdot \text{K}$ from -130 to 20 °C (-200 to 68 °F).

(i) Stated value represents average coefficient between 20 and 260 °C (68 and 500 °F).

- (j) Stated value represents average coefficient between 20 and 540 °C (68 and 1000 °F).
- (k) Stated value represents average coefficient between -18 and 95 °C (0 and 200 °F).
- (l) Stated value represents average coefficient between -18 and 650 °C (0 and 1200 °F).
- (m) 11.2 $\mu\text{m/m} \cdot \text{K}$ from -100 to 20 °C (-148 to 68 °F); 10.4 $\mu\text{m/m} \cdot \text{K}$ from -150 to 20 °C (-238 to 68 °F).
- (n) Stated value represents average coefficient between 20 and 205 °C (68 and 400 °F).
- (o) Stated value represents average coefficient between 20 and 315 °C (68 and 600 °F).
- (p) Stated value represents average coefficient between 25 and 270 °C (77 and 518 °F).
- (q) Stated value represents average coefficient between 20 and 275 °C (68 and 525 °F).
- (r) Stated value represents average coefficient between -18 and 260 °C (0 and 500 °F).
- (s) Stated value represents average coefficient between -18 and 540 °C (0 and 1000 °F).

Introduction

CARBON AND LOW-ALLOY STEEL SHEET AND STRIP have much in common with, but also some significant differences from, their flat-rolled plate counterparts. Categorizing these products on the basis of dimensions alone is impossible because of their interchangeability and the overlapping of sizes. Mechanical processing must also be taken into consideration when classifying these hot mill products. Generally, sheet and strip are produced as coils that are rolled in only one direction while using water to accelerate cooling. Plate products, on the other hand, are made from slabs that can be cross rolled (rolled parallel and perpendicular to the slab length) and that are air cooled. Plate is available in widths up to 5080 mm (200 in.). Strip refers to hot-rolled coils less than 305 mm (12 in.) wide or cold-rolled coils less than 608 mm (23 $\frac{15}{16}$ in.) wide. The maximum sheet width currently available from most manufacturers is 1830 mm (72 in.), although a few manufacturers have the capability of producing 1930 mm (76 in.) wide sheet in a 2130 mm (84 in.) mill facility.

Plain Carbon Steel

Plain carbon steel sheet and strip are used primarily in consumer goods. These applications require materials that are serviceable under a wide variety of conditions and that are especially adaptable to low-cost techniques of mass production into articles having good appearance. Therefore, these products must incorporate, in various degrees and combinations, ease of fabrication, adequate strength, excellent finishing characteristics to provide attractive appearance after fabrication, and compatibility with other materials and with various coatings and processes.

The steels used for these products are supplied over a wide range of chemical compositions (see Tables 1 and 2); however, the vast majority are unalloyed, low-carbon steels selected for stamping applications, such as automobile bodies

and appliances. Thus, this section of the article will focus on low-carbon steel applications. For these major applications, typical compositions are 0.03 to 0.10% C, 0.15 to 0.50% Mn, 0.035% P (max), and 0.04% S (max).

(a) All values are maximum.

(b) CR, cold rolled; HR, hot rolled; SQ, structural quality; DQ, drawing quality; DQSK, drawing quality, special killed; CQ, commercial quality.

(c) Copper when specified as copper-bearing steel; 0.20% min.

(d) Aluminum as deoxidizer usually exceeds 0.010% in the product.

(e) Killed steel can be supplied upon request to the manufacturer for grades D through G. When silicon-killed steel is specified, a range of 0.15-0.30% Si shall be supplied.

Generally, rimmed (or capped) ingot cast steel has been used because of its lower price. More recently, these steels have been replaced by killed steels produced by the continuous casting process. This process is inherently suited to the production of killed steels. Where strain aging is to be avoided and/or when exceptional formability is required, steel killed with aluminum, regardless of the method of casting or manufacture, is preferred. Further details regarding steelmaking and deoxidation practice are given in the articles "Steel Processing Technology" and "Classification and Designation of Carbon and Low-Alloy Steels" in this Volume.

The width differentiation between sheet and strip made of plain carbon steel depends on the rolling process. It should be noted that both sheet and strip can be purchased as either cut lengths or coils. The standard dimensional tolerances for plain carbon steel strip are more restrictive than those for sheet. Standard size ranges of plain carbon steel sheet and strip are given in Table 3. Typical characteristics of the various qualities of these products are listed in Table 4(a), 4(b), and 4(c).

Table 3 Classification of hot-rolled and cold-rolled plain carbon steel sheet and strip product by size

Product	Thickness		Width		Other limitations	Specification symbol (ASTM No.)

(a) See Table 4(b).

(b) See Table 4(c).

(c) No symbol necessary; cut edge is standard.

(d) Produced in five tempers with specific hardness and bend test limits; composition subordinate to mechanical properties.

Table 4(b) Selection and specification of surface condition for plain carbon steel sheet

Specification symbol	Description of surface	Surface described applicable to
U ^(a)	Surface finish as normally used for unexposed automotive parts. Matte appearance. Normally annealed last	Cold-rolled sheet
E ^(b)	Surface finish as normally used for exposed automotive parts that require a good painted surface. Free from strain markings and fluting. Matte appearance. Temper rolled	Cold-rolled sheet
B	Same as above, except commercial bright appearance	Cold-rolled sheet
L	Same as above, except luster appearance	Cold-rolled sheet
1	No. 1 or dull finish (no luster). Especially suitable for lacquer or paint adhesion. Facilitates drawing by reducing the contact friction between the die and the metal	Cold-rolled strip
2	No. 2 or regular bright finish (moderately smooth). Suitable for many applications, but not generally applicable for parts to be plated, unless polished and buffed	Cold-rolled strip
3	No. 3 or best bright finish (relatively high luster). Particularly suitable for parts to be plated	Cold-rolled strip
A	As-rolled or black (oxide or scale not removed)	Hot-rolled sheet and strip
P	Pickled (scale removed), not oiled	Hot-rolled sheet and strip
O	Same as above, except oiled	Hot-rolled sheet and strip

Source: Ref 2

(a) U, unexposed; also designated as class 2, cold-rolled sheet.

(b) E, exposed; also designated as class 1, cold-rolled sheet.

Table 4(c) Selection and specification of edge condition of plain carbon steel sheet and strip

Specification symbol	Description of edge	Edge described applicable to
None required	Cut edge	Cold-rolled sheet

1	No. 1 edge is a prepared edge of a specified contour (round, square, or beveled) supplied when a very accurate width is required or where the finish of the edge is required to be suitable for electroplating or both	Cold-rolled strip
2	No. 2 edge is a natural mill edge carried through the cold rolling from the hot-rolled strip without additional processing of the edge	Cold-rolled strip
3	No. 3 edge is an approximately square edge produced by slitting, on which the burr is not eliminated	Cold-rolled strip
4	No. 4 edge is a rounded edge produced by edge rolling the natural edge of hot-rolled strip or slit-edge strip. This edge is produced when the width tolerance and edge condition are not as exacting as for No. 1 edge	Cold-rolled strip
5	No. 5 edge is an approximately square edge produced by rolling or filing of a slit edge to remove burr only	Cold-rolled strip
6	No. 6 edge is a square edge produced by edge rolling the natural edge of hot-rolled strip or slit-edge strip, where the width tolerance and finish required are not as exacting as for No. 1 edge	Cold-rolled strip
M	Mill edge	Hot-rolled sheet and strip
C	Cut edge	Hot-rolled sheet and strip
S	Square edge (square and smooth, corners slightly rounded). Produced by rolling through vertical edging rolls during the hot-rolling operation	Hot-rolled strip

Source: Ref 2

Production of Carbon Steel Sheet and Strip

Carbon steel sheet and strip are available as hot-rolled and as cold-rolled products. Hot-rolled low-carbon steel sheet and strip are usually produced on continuous hot strip mills. The slab is heated and then passed through the mill, where the thickness is progressively reduced to the desired final dimension (see Fig. 3 and the corresponding text in the section "Direct Casting Methods" in this article). Some wide hot strip mills are capable of producing low-carbon steel sheet in thicknesses as low as 1.214 mm (0.0478 in.) (18 gage), but 1.897 mm (0.0747 in.) (14 gage) is considered a practical lower limit. Most narrow hot-strip mills are capable of producing low-carbon steel strip in thicknesses as low as 1.062 mm (0.0418 in.) (19 gage).

Cold-rolled low-carbon steel sheet and strip are produced from pickled hot-rolled coils by cold reduction to the desired thicknesses in either a continuous tandem mill or a reversing cold-reduction mill. The cold-rolling process allows thinner gages to be produced than can be obtained by hot rolling. Other advantages of cold-rolled steel are its better surface finish and dimensional control. The as-rolled steel is hard and has low productivity. Except when a fully work-hardened condition is desired, the steel is annealed to optimize its formability. This annealing can be range from stress relieving through full recrystallization with ferrite grain growth and carbide agglomeration (see the article "Steel Processing Technology" in this Volume). After annealing, temper rolling (also called skin rolling or skin passing) is usually done to improve flatness and surface finish. Roller leveling or tension leveling can be used to improve flatness. Temper rolling, roller leveling, or tension leveling will also minimize the tendency of the material to develop stretcher strains during forming; this effect is permanent with killed steels and temporary with rimmed and capped steels (see the section "Surface Characteristics" in this article). Heating a killed steel, as in baking paint, may cause the steel to become susceptible to stretcher strains (see the article "Precoated Steel Sheet" in this Volume).

Most cold-rolled low-carbon steel sheet is available in two classes (Table 4(a)). Class 1 (temper rolled) is intended for applications where surface appearance is important and where specified surface and flatness requirements must be met. Class 2 is a product intended for applications where appearance is less important. Cold-rolled low-carbon steel strip is available in five hardness tempers ranging from full hard to dead soft (Table 5).

Table 5 Mechanical properties of cold-rolled low-carbon steel strip (ASTM A 109)

Temper	Hardness requirements, HRB	Bent test requirements ^(a)	Approximate tensile strength		Elongation in 50 mm (2 in.), % ^(b)
			MPa	ksi	
No. 1 (hard)	90 minimum ^(c) , 84 minimum ^(d)	No bending in either direction	550-690	80-100	...
No. 2 (half-hard)	70-85 ^(d)	90° bend across rolling direction around a $1t$ radius	380-520	55-75	4-16
No. 3 (quarter-hard)	60-75 ^(e)	180° bend across rolling direction and 90° bend along rolling direction, both around a $1t$ radius	310-450	45-65	13-27
No. 4 (skin rolled)	65 maximum ^(e)	Bend flat on itself in any direction	290-370	42-54	24-40
No. 5 (dead)	55 maximum^(e)	Bend flat on itself in any direction	260-	38-50	33-45

(a) t = thickness of strip.

(b) For strip 1.27 mm (0.050 in.) thick.

(c) For strip of thickness 1.02-1.78 mm exclusive (0.040-0.070 in. exclusive).

(d) For strip of thickness 1.78-6.35 mm exclusive (0.070-0.250 in. exclusive).

(e) For strip of thickness 1.02-6.35 mm exclusive (0.040-0.250 in. exclusive)

Quality Descriptors for Carbon Steels

The descriptors of quality used for hot-rolled plain carbon steel sheet and strip and cold-rolled plain carbon steel sheet include structural quality, commercial quality, drawing quality, and drawing quality, special killed (Table 4(a)). Some of the as-rolled material made to these qualities is subject to surface disturbances known as coil breaks, fluting, and stretcher strains; however, fluting and stretcher strains will not be produced during subsequent forming if the material is temper rolled and/or roller leveled immediately prior to forming. It should be noted that any beneficial effects of roller leveling deteriorate rapidly in nonkilled steel. In addition to the requirements listed below for the various qualities of plain carbon steel sheet and strip, special soundness can also be specified.

Commercial quality (CQ) plain carbon steel sheet and strip are suitable for moderate forming; material of this quality has sufficient ductility to be bent flat on itself in any direction in a standard room-temperature bend test. Commercial

quality material is not subject to any other mechanical test requirements, and it is not expected to have exceptionally uniform chemical composition or mechanical properties. However, the hardness of cold-rolled CQ sheet is ordinarily less than 60 HRB at the time of shipment.

Drawing Quality. When greater ductility or more uniform properties than those afforded by commercial quality are required, drawing quality (DQ) is specified. Drawing quality material is suitable for the production of deep-drawn parts and other parts requiring severe deformation. When the deformation is particularly severe or resistance to stretcher strains is required, drawing quality, special killed (DQSK) is specified. When either type of drawing quality material is specified, the supplier usually guarantees that the material is capable of being formed into a specified part within an established breakage allowance. The identification of the part is included in the purchase order. Ordinarily, DQ or DQSK material is not subject to any other mechanical requirements, nor is it normally ordered to a specific chemical composition.

Special killed steel is usually an aluminum-killed steel, but other deoxidizers are sometimes used to obtain the desired characteristics. In addition to severe drawing applications, it is specified for applications requiring freedom from significant variations in mechanical properties or freedom from fluting and stretcher strains in temper-rolled material without subsequent roller leveling prior to forming. Special killed steels also have inherent characteristics that increase their formability.

Structural quality (SQ), formerly called physical quality (PQ), is applicable when specified strength and elongation values are required in addition to bend tests (Table 6). Minimum values of tensile strength ranging up to 690 MPa (100 ksi) in hot-rolled sheet and strip and up to 1035 MPa (150 ksi) in cold-rolled sheet are available. Cold-rolled strip, which does not have a quality descriptor, is available in five tempers that conform to specified Rockwell hardness ranges and bend test requirements (Table 5). It should be noted that steels with yield strengths exceeding 275 MPa (40 ksi) or tensile strengths greater than 345 MPa (50 ksi) are referred to as high-strength structural or high-strength low-alloy steels. These materials are described elsewhere in this Section of the Volume (see the articles "Classification and Designation of Carbon and Low-Alloy Steels" and "High-Strength Structural and High-Strength Low-Alloy Steels").

Table 6 Tensile requirements for hot-rolled and cold-rolled plain carbon steel sheet and strip

Class or grade	Yield strength, minimum		Tensile strength, minimum		Elongation in 50 mm (2 in.), minimum, %
	MPa	ksi	MPa	ksi	
Structural quality hot-rolled sheet and strip in cut lengths or coils (ASTM A 570) ^(a)					
30	205	30	340	49	25.0 ^(b)

Source: Ref 1

- (a) For coil products, testing by the producer is limited to the end of the coil. Results of such tests must comply with the specified values. However, design considerations must recognize that variation strength levels may occur throughout the untested portions of the coil, but generally these levels will not be less than 90% of the minimum values specified.
- (b) At thickness, t , of 2.5-5.9 mm (0.097-0.230 in.).
- (c) On this full-hard product, the yield point approaches the tensile strength and because there is no halt in the gage or drop in the beam, the yield point shall be taken as the stress at 0.5% elongation, under load.
- (d) Yield strength determined by the 0.2% offset or 0.5% extension under load methods.
- (e) At thickness, t , of 3.7-5.9 mm (0.145-0.230 in.).

Mechanical Properties of Carbon Steels

The commonly measured tensile properties of plain carbon steel sheet and strip are not readily related to their performance in fabrication; the relationship between formability and values of the strain-hardening exponent, *n*, and the plastic strain ratio, *r* (determined in tensile testing), is discussed in the article "Sheet Formability of Steels" in this Volume. The mechanical properties of commercial quality, drawing quality, and drawing quality, special killed sheet and strip are not ordinarily used in specifications unless special strength properties are required in the fabricated product. As a matter of general interest, however, the ranges of mechanical properties typical of sheet produced by three mills in these qualities are shown in Fig. 1. The bands would be wider if the product of the entire industry were represented.

Fig. 1 Typical mechanical properties of low-carbon steel sheet shown by the range of properties in steel furnished by three mills. Hot-rolled sheet thickness from 1.519 to 3.416 mm (0.0598 to 0.1345 in., or 16 to 10 gage); cold-rolled sheet thickness from 0.759 to 1.519 mm (0.0299 to 0.0598 in., or 22 to 16 gage). All cold-rolled grades include a temper pass. All grades were rolled from rimmed steel except the one labeled special killed. See Table 5 for the mechanical properties of structural (physical) quality sheet.

It should be noted that the ranges are broader and the sheet harder for the hot-rolled than for the cold-rolled materials and that cold-rolled drawing quality, special killed sheet is produced to a narrower range of mechanical properties than cold-rolled drawing quality sheet, which is a rimmed steel grade. There is a great deal of overlapping in properties between commercial quality and drawing quality sheet.

Figure 2 shows the relationships among hardness, Olsen ductility, and sheet thickness in commercial quality and drawing quality hot-rolled low-carbon steel sheet, indicating the variations in properties that can occur in these materials. Stretchability, as measured by the Olsen value, is also shown to increase as sheet thickness increases.

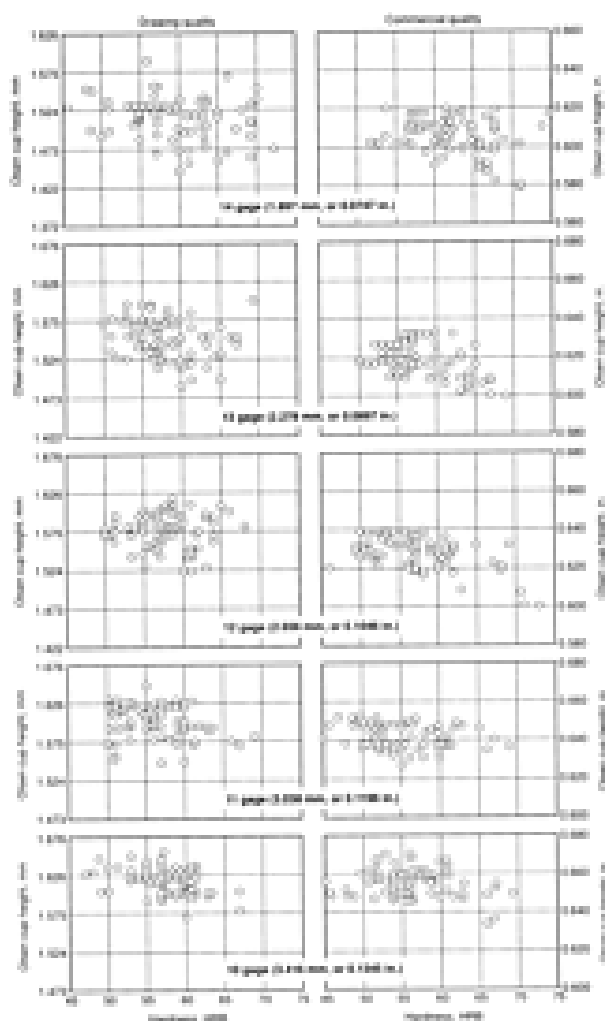

Fig. 2 Scatter in Olsen ductilities of hot-rolled low-carbon steel sheet

In contrast to commercial and drawing quality materials, structural (physical) quality sheet and strip are produced in many grades having specific mechanical property minimums, seven of which are shown in Table 6. Cold-rolled low-carbon steel strip is not usually produced to specific strength requirements; typical mechanical property ranges for the various tempers of this product are listed in Table 5.

Mill Heat Treatment of Cold-Rolled Products

Unless a hard temper is desired, cold-rolled carbon steel sheet and strip are always softened to improve formability. This is usually accomplished at the mill by a recrystallization heat treatment such as annealing or normalizing.

Annealing. Low-temperature recrystallization annealing, or process annealing, can be used to soften cold-rolled low-carbon steel. When done as a batch process, this type of annealing is known as box annealing. It is carried out by placing coils on a bottom plate and then enclosing them with a cover within which a protective gas atmosphere is maintained. A bell-type heating furnace is then placed over the atmosphere container. After heating to approximately 595 to 760 °C (1100 to 1400 °F), the charge is allowed to soak until the temperature is uniform throughout. The heating furnace is then removed, and the charge is allowed to cool in the protective atmosphere before being uncovered.

Cold-rolled steel can be batch annealed in coil form under a protective atmosphere. Some producers use a 100% hydrogen atmosphere in an effort to shorten annealing cycles.

Instead of box annealing, coils can also be treated by continuous annealing. With this process, which is usually intended to provide a fully recrystallized grain structure, coils are unwound and passed through an annealing furnace. The uncoiled

steel strip passes through several different thermal zones of the furnace that serve to heat, soak, and cool the steel before it exits the furnace and is recoiled. This anneal cycle is very rapid and can be measured in seconds or minutes (as opposed to hours or days with a box anneal cycle). Generally, the rapid anneal cycle of a continuous anneal process results in material properties that are less ductile than those resulting from a box anneal cycle. However, continuous annealing results in more uniformity of properties throughout the length of a coil.

Open-coil annealing is used when uniform heating and/or gas contact across the entire width of the coil is required (for example, to obtain decarburization over the entire surface during production of material for porcelain enameling). In this process, the coils are loosely wound, permitting gas to flow freely between the coil convolutions. Annealing temperatures may be higher than those used in conventional box annealing.

Normalizing consists of heating the sheet or strip to a temperature above the Ac_3 point ($\sim 925^\circ\text{C}$, or 1700°F , for a steel that contains less than 0.15% C) in a continuous furnace containing an oxidizing atmosphere, then cooling to room temperature at a controlled rate (usually in still air). This treatment recrystallizes and refines the grain structure by phase transformation. Low-metalloid steel (enameling iron) for porcelain enameling is normalized rather than annealed because this steel will not readily recrystallize at box-annealing temperatures.

Surface Characteristics

The surface texture of low-carbon cold-rolled steel sheet and strip can be varied between rather wide limits. For chromium plating and similar finishes, a smooth, bright sheet or strip surface is necessary, but for porcelain enameling and many drawing operations, a rougher surface texture (matte finish) is preferred. In porcelain enameling, roughness tends to improve the adherence and uniformity of the coating; in certain drawing operations where heavy pressures are developed, the rougher type of surface is believed to retain more lubricant, thus aiding formation of the sheet by reducing friction and die galling.

Minor surface imperfections and slight strains are less noticeable on a dull surface than on a bright one. However, the surfaces of parts to be painted should not be so rough that the paint will not cover them adequately. A very smooth, bright surface can be obtained on sheet or strip by utilizing ground and polished rolling-mill rolls, and a dull (matte) surface can be obtained by either grit blasting or etching the rolls. For the purpose of evaluating surface roughness, an appropriate instrument is employed that measures the average height of surface asperities (peaks) in microinches and the number of peaks per inch that exceed a given height.

Cold-rolled sheet or strip can also be purchased with coined patterns that form a geometric design or that simulate such textures as leather grain. Such products are available in commercial quality, drawing quality, and drawing quality, special killed material. The texture is rolled into the steel surface after the sheet or strip has been annealed and thus has an effect on properties similar to that of a heavy temper-rolling pass. This effect, plus the notch effect of the pattern itself, somewhat reduces the formability of the sheet or strip.

Stretcher Strains. When loaded in tension, practically all hot-rolled or as-annealed cold-rolled plain carbon steels, whether rimmed, capped, or killed, exhibit a sharp upper yield point, a drop in load to the lower yield point, and subsequent plastic deformation at a nearly constant load (known as yield point elongation). The plastic deformation that occurs within this yield point elongation is accompanied by the formation of visible bands of deformation on the product surfaces. These bands are called stretcher strains or Lüders lines, and they can be aesthetically undesirable.

The tendency for stretcher strains to occur can be prevented through elimination of yield point elongation. In rimmed or capped steels, this is accomplished by subjecting the steel to small amounts of plastic deformation, usually by temper rolling, tension leveling, and/or roller leveling. Because overstraining the steel by these practices can increase strength and generally decrease ductility, it is usually desirable to strain the steel only by the amount required to eliminate yield point elongation. When properly processed, a killed steel, such as DQSK, provides a product with no yield point elongation.

Strain Aging. In rimmed or capped (but not killed) carbon steels, deformation (such as by temper rolling) following by aging for several days or more at or slightly above room temperature will result in a return of the upper yield point and yield point elongation, increases in yield and tensile strengths, and a decrease in ductility. This treatment, called strain aging, may be desirable if the increase in strength can be used to advantage. However, strain aging often causes problems due to reduced formability and stretchability and the return of both yield point elongation and a propensity for stretcher strains. Further temper rolling may eliminate yield point elongation, but it will not restore stretchability. In applications

where the appearance of stretcher strains is objectionable, killed steels, which are resistant to aging, are preferable to rimmed and capped steels. For ingot casting, however, rimmed and capped steels are generally superior in inherent surface quality, are lower in cost, and are preferred over killed steel as long as the occurrence of stretcher strains is not a problem.

Strain aging is related to the presence of nitrogen in solid solution in the steel and is affected by time and temperature, with longer times and higher temperatures producing greater aging. The strain-aging rate is also dependent on the amount of deformation that has occurred and is increased when the deformation occurs at higher temperatures or lower strain rates. Another important variable that affects strain aging is the amount of nitrogen in solution. Killed carbon steels have very little susceptibility to strain aging because their nitrogen content is essentially chemically combined with aluminum. Rimmed and capped steels, however, tend to strain age because they contain greater amounts of nitrogen in solid solution (typically 6 to 30 ppm).

Control of Flatness

Plain carbon steel sheet is ordinarily sold to two standards of flatness:

- Commercial flatness, which is used where flatness is important but not critical
- The stretcher-level standard of flatness, which is required when little or no forming is to be done and the product is required to be flat and free from waves or oil can, or when flatness is necessary to ensure smooth automatic feeding of forming equipment.

The permissible variations for the flatness of hot- and cold-rolled sheet have been established by the Technical Committee of the American Iron and Steel Institute and are given in the AISI Steel Products Manual. Commercial flatness can usually be produced by roller leveling or by temper rolling and roller leveling, but where very flat sheet is required, producers may have to resort to stretcher leveling, tension leveling, or other leveling processes.

In temper rolling, the steel is cold reduced, usually by $\frac{1}{2}$ to 2%, which is also effective for removing yield point elongation and preventing stretcher strains.

In roller leveling, a staggered series of small-diameter rolls alternately flexes the steel back and forth. The rolls are adjusted so that the greatest deformation occurs at the entrance end of the rolls and less flexing occurs at the exit end. Stretcher strains can also be eliminated by roller leveling, as long as the deformation is great enough to remove yield point elongation. Dead-soft annealed sheet cannot be made suitable for production of exposed parts by roller leveling because the rolls kink the sheet severely, producing leveler breaks. The deformed areas or kinks will not deform further upon stretching and will appear as braised welts after forming.

Stretcher Leveling. Leveling by stretching cut lengths of the temper-rolled sheet lengthwise between jaws (stretcher leveling) is a more positive means of producing flatness. Elongation (stretching) during stretcher leveling may vary from about 1 to 3%, which exceeds the elastic limit of the steel and therefore results in some permanent elongation. The sheet must be of a killed or a capped steel having nearly uniform properties so that it will spring back uniformly across its full width and remain flat. It may be necessary to use killed steel having nearly uniform properties so that, after stretching, strain markings do not develop.

Tension Leveling. Another flattening process that is used for steel sheet is tension leveling, which combines the effects of stretcher and roller leveling. The sheet is pulled to a stress near its yield point while it is simultaneously flexed over small rolls; the combined tension and bending produce yielding at the flex points.

Modified Low-Carbon Steel Sheet and Strip

In addition to the low-carbon steel sheet and strip products already discussed in this article, there are numerous additional products available that are designed to satisfy specific customer requirements. These products are often made with low-carbon steels having chemical compositions slightly modified from those discussed earlier.

To be considered a plain low-carbon grade, a steel should contain no more than 0.25% C, 1.65% Mn, 0.60% S, and 0.60% Cu, but it may also contain small amounts of other elements, such as nitrogen, phosphorus, and boron, that are effective in imparting special characteristics when present singly or in combination. The modified low-carbon steel grades discussed below are designed to provide sheet and strip products having increased strength, formability, and/or corrosion resistance.

Carbon-Manganese Steels. Manganese is a solid-solution strengthening element in ferrite and is also effective in increasing hardenability. Manganese in amounts ranging from 1.0 to 1.5% is added to low-carbon steel (0.15 to 0.25% C) to provide enhanced strength (yield strength of about 275 MPa, or 40 ksi) with good ductility in hot-rolled and cold-rolled sheet and strip. Components fabricated from these higher-manganese steels can be heat treated by quenching and tempering to provide enhanced strength with good toughness (see the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume).

Carbon-Silicon Steels. Silicon, like manganese, is an effective ferrite-strengthening element and is sometimes added in amounts of about 0.5%, often in combination with 1.0 to 1.5% Mn, to provide increased strength in low-carbon hot-rolled and cold-rolled steel sheet and strip.

Nitrogenized and Rephosphorized Steels. Nitrogen is a strong interstitial strengthener, and phosphorus is an effective solid-solution strengthener in ferrite. Either about 0.010 to 0.015% N or 0.07 to 0.12% P is added to low-carbon steel to provide hot-rolled and cold-rolled sheet and strip with yield strength in the range of 275 to 345 MPa (40 to 50 ksi) for low-cost structural components for buildings and automotive uses. Formed parts produced from nitrogenized steel can be further strengthened to yield strengths in the range of 415 to 485 MPa (60 to 70 ksi) as the result of strain aging that occurs at paint-curing temperatures.

Boron Steels. Boron is a strong carbide- and nitride-forming element and increases strength in quenched and tempered low-carbon steels through the formation of martensite and the precipitation strengthening of ferrite. Boron-containing killed carbon steels are available as low-cost replacements for the high-carbon and low-alloy steels used for sheet and strip. The low-carbon boron steels have better cold-forming characteristics and can be heat treated to equivalent hardness and greater toughness for a wide variety of applications, such as tools, machine components, and fasteners.

Copper Steels. Copper in amounts up to 0.5% is not only a mild solid-solution strengthener in ferrite, but it also provides enhanced atmospheric corrosion resistance together with improved paint retention in applications involving full exposure to the weather. Therefore, copper-bearing (0.20% Cu, minimum) steel is often specified by customers for use in sheet and strip for structures subject to atmospheric corrosion. Essentially all low-carbon steel sheet and strip products can be supplied in copper-bearing grades, if so specified. Copper-bearing steels, which are also referred to as weathering steels, are also described in the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume.

Low-Alloy Steel**

Low-alloy steel sheet and strip are used primarily for those special applications that require the mechanical properties normally obtained by heat treatment. A sizeable selection of the standard low-alloy steels are available as sheet and strip, either hot-rolled or cold rolled. The most commonly available alloys are listed in Table 7, along with their chemical compositions. In addition to standard low-alloy steels, high-strength low-alloy (HSLA) and dual-phase steels are available as sheet or strip for applications requiring tensile strengths in the range of 290 to 760 MPa (42 to 110 ksi), and ultrahigh-strength steels or maraging steels for applications requiring tensile strengths above 1380 MPa (200 ksi). These steels are discussed in the articles "High-Strength Structural and High-Strength Low-Alloy Steels," "Dual-Phase Steels," "Ultrahigh-Strength Steels" and "Maraging Steels" in this Volume.

(b) Other silicon ranges are available. Consult the producer.

Production of Sheet and Strip

As described earlier in this article, steel sheet and strip are flat-rolled products that can be rolled to finished thickness on either a hot mill or a cold mill. Hot-rolled steel sheet and strip are normally produced by passing heated slabs through a continuous mill consisting of a series of roll stands, where the thickness is progressively reduced to the desired final dimension.

Cold-rolled low-alloy steel sheet and strip are normally produced from pickled and annealed hot-rolled bands of intermediate thickness by cold reduction to desired thickness in a single-stand mill or tandem mill. Intermediate anneals may be required to facilitate cold reduction or to obtain the mechanical properties desired in the finished product. Cold rolling can produce thinner gages than can be obtained by hot rolling.

Low-alloy steel sheet and strip are produced in thicknesses similar to those typical of HSLA steel sheet and strip (Table 8). In general, tolerances similar to those given in the general requirements for hot-rolled and cold-rolled low-alloy and HSLA steel sheet and strip, ASTM A 505, apply to all low-alloy and HSLA steel sheet and strip. Available thicknesses

and tolerances may vary among producers, due mainly to the interrelation between steel quality and rolling practice, as influenced by the equipment available for rolling the product.

Table 8 Standard sizes of hot-rolled and cold-rolled low-alloy steel sheet and strip: regular quality, structural quality, and drawing quality

Product	Applicable ASTM specification	Thickness range		Width range	
		mm	in.	mm	in.
Hot-rolled sheet	A 506, A 507	5.839-4.572 inclusive	0.2299-0.1800 inclusive	610-1220 inclusive	24-48 inclusive
		≤ 4.569	≤ 0.1799	>610	>24
Hot-rolled strip	A 506, A 507	≤ 5.156	≤ 0.2030	≤ 152	≤ 6
		≤ 5.839	≤ 0.2299	152-608 inclusive	>6-23 $\frac{15}{16}$ inclusive
Cold-rolled sheet	A 506, A 507	≤ 5.839	≤ 0.2299	610-1220	24-48
		≤ 4.569	≤ 0.1799	>1220	>48
Cold-rolled strip	A 506, A 507	≤ 6.347	≤ 0.2499	≤ 608	≤23 $\frac{15}{16}$

Quality Descriptors

As it is used for steel mill products, the term quality relates to the general suitability of the mill product to make a given class of parts. For low-alloy steel sheet and strip, the various quality descriptors imply certain inherent characteristics, such as the degree of internal soundness and the relative freedom from harmful surface imperfections.

The quality descriptors used for alloy steel sheet and plate include regular quality, drawing quality, and aircraft quality, which are covered by ASTM specifications. The general requirements for these qualities include bearing quality and aircraft structural quality. Aircraft quality requirements are also defined in Aerospace Material Specifications (AMS).

Regular Quality. Low-alloy steel sheet and strip of regular quality are intended principally for general or miscellaneous applications where moderate drawing and/or bending is required. A smooth finish free of minor surface imperfections is not a primary requirement. Sheet and strip of this quality do not have the uniformity, the high degree of internal soundness, or the freedom from surface imperfections that are associated with other quality descriptors for low-alloy sheet and strip.

Regular quality low-alloy steel sheet and strip are covered by ASTM A 506. One or more of the following characteristics may be specified by the purchaser: chemical composition, grain size, or mechanical properties (determined by tensile and bend tests.)

Drawing quality describes low-alloy steel sheet and strip for applications involving severe cold working such as deep-drawn or severely formed parts. Drawing quality low-alloy sheet and strip are rolled from steel produced by closely controlled steelmaking practices. The semifinished and finished mill products are subject to testing and inspection

designed to ensure internal soundness, relative uniformity of chemical composition, and freedom from injurious surface imperfections. Spheroidize annealing is generally specified so the mechanical properties and microstructure are suitable for deep drawing or severe forming. Drawing quality low-alloy steel sheet and strip are covered by ASTM A 507.

No standard test can fully evaluate resistance to breakage during deep drawing because successful drawing is affected by die clearances, die design, speed of drawing, lubricants, ironing, grade of steel, and any alteration of hardness, ductility, or surface condition that may develop during drawing. Thus, it cannot be assumed that merely specifying drawing quality steel will ensure a capability for drawing or forming a specific part under a given set of manufacturing conditions. Manufacturing trials may be necessary before purchase orders can be written for production material.

Bearing quality describes low-alloy steel sheet and strip intended for antifriction bearing parts. The steels are generally AISI-SAE alloy carburizing grades or AISI-SAE high-carbon chromium grades. These steels are produced using steelmaking and conditioning practices that are intended to optimize internal soundness and to provide a known size, shape, and distribution of non-metallic inclusions. Standards of acceptance for microstructural quality are commonly reviewed and agreed upon between producer and purchaser for each order. Alternatively, internal soundness and microcleanliness can be determined by using immersion ultrasonic testing techniques to agreed-upon acceptance standards. More detailed information on low-alloy bearing steels can be found in the article "Bearing Steels" in this Volume.

Aircraft quality describes low-alloy steel sheet and strip for important or highly stressed parts of aircraft, missiles, and similar applications involving stringent performance requirements, especially in terms of internal cleanliness. The special mill practices required for producing aircraft quality sheet and strip include careful selection of the raw materials charged into the melting furnace, exceptionally close control of the steelmaking process, cropping and discarding more of the ingot than is normal during primary reduction, selection of specific heats or portions of heats for fulfillment of a given customer order, and using exceptionally close control over process variables during reheating and rolling. Aircraft quality low-alloy steel sheet and strip generally have an austenitic grain size predominantly ASTM No. 5 or finer, with grains as coarse as ASTM No. 3 permissible. Grain size tests are normally made on rerolling slabs or billets.

Aircraft quality low-alloy steel sheet and strip are covered by Aerospace Material Specifications (AMS 6454A, for example). Material of this quality is ordinarily certified that it has been produced as aircraft quality.

Aircraft structural quality low-alloy steel sheet and strip meet all the requirements of aircraft quality mill products described above. In addition, they meet specified requirements for mechanical properties, which may include tensile strength, yield strength, elongation, bend test results, or results of other similar tests. Many specimens from each heat must be tested to ensure compliance with the required mechanical properties.

Mill Heat Treatment

Hot-rolled regular quality low-alloy steel sheet and strip are normally available from the producer either as-rolled or heat treated. Standard mill heat-treated conditions are annealed, normalized, or normalized and tempered. Cold-rolled regular quality product is normally available only in the annealed condition.

Hot-rolled and cold-rolled drawing quality alloy steel sheet and strip are normally furnished by the producer in the spheroidize-annealed condition. They can be purchased in the as-rolled condition if they are to be spheroidize annealed by the user.

Aircraft quality products are normally furnished in a heat-treated condition. Hot-rolled products may be annealed, spheroidize annealed, normalized, or normalized and tempered by the producer. Cold-rolled products are normally furnished only in the annealed or spheroidize-annealed condition.

Annealing is done by heating the steel to a temperature near or below the lower critical temperature and holding at that temperature for a sufficient period, followed by slow cooling in the furnace. This process softens the sheet or strip for further processing, but not to the same degree as spheroidize annealing.

Spheroidize annealing involves prolonged heating at a temperature near or slightly below the lower critical temperature, followed by slow cooling. The objective of this process is to change the form of the carbides in the microstructure to a globular (spheroidal) shape, which produces the greatest degree of softening.

Normalizing consists of heating the sheet or strip to a temperature 55 to 70 °C (100 to 125 °F) above A_{c3} and then cooling to room temperature at a controlled rate (usually in still air). This treatment recrystallizes and refines the grains by phase transformation and can be used to obtain the desired mechanical properties.

Tempering consists of reheating steel to a predetermined temperature below the lower critical temperature, holding for a specified length of time, and then cooling under suitable conditions. When it is carried out as part of a mill heat treatment, tempering is done after normalizing to obtain the desired mechanical properties by modifying the as-normalized microstructure.

Quenching and tempering (or hardening) is normally reserved for the user to apply as one of the final steps in the fabricating process.

Mechanical Properties

In most instances, the mechanical properties of low-alloy steel furnished by the producer are of little consequence because they will be altered by heat treatment during fabrication. For low-alloy steel sheet and strip to be used in the mill condition, mechanical properties will vary, depending on both chemical composition and mill processing. Table 9 lists typical tensile properties for chromium-molybdenum low-alloy steel sheet and strip used for pressure vessels. Usually, low-alloy steel sheet and strip are custom produced to fulfill specific customer orders. Where necessary, any mechanical property requirements can be made part of the purchase order.

Table 9 Tensile requirements of chromium-molybdenum alloy steel sheet and strip for pressure vessels (ASTM A 873)

Class	Yield strength, minimum		Tensile strength, minimum		Elongation in 50 mm (2 in.), minimum, at thickness t , %	
	MPa	ksi	MPa	ksi	$t=3.8-5.9$ mm (0.145-0.230 in.)	$t=1.8-3.7$ mm (0.070-0.144 in.)
1	205	30	415	60	15	12
2	310	45	515	75	13	10
3	415	60	585	85	12	9
4	515	75	655	95	11	8
5	690	100	895	130	7	4

Source: Ref 1

Because the chief benefits of low-alloy steel sheet and strip accrue to the user only after the finished part is heat treated, the mechanical properties of heat-treated low-alloy steels are the ones of greatest importance. These properties can be determined from hardenability curves (see the article "Hardenability Curves" in this Volume) and heat-treating guides such as those found in the articles "Hardenable Carbon and Low-Alloy Steels" and "Hardenability of Carbon and Low-Alloy Steels" in this Volume. In general, only those properties typical of through-hardened steel of the specific grade under consideration need to be considered. Except for the most shallow hardening grades used at thicknesses at or near the upper limit for sheet and strip, parts made of low-alloy steel sheet or strip will through harden when quenched. Many grades will through harden when quenched in a slow medium such as oil and may even through harden when air cooled. The possibility of oil quenching or air cooling should always be considered for hardening thin parts, especially when warping or distortion during hardening need to be minimized.

Parts made of low-alloy steel sheet and strip are sometimes carburized or carbonitrided to improve the mechanical properties or wear resistance of the surface layer. In some cases, parts that are difficult to form when made of a medium-carbon low-alloy steel can be formed from low-carbon low-alloy steel and then carburized to a uniform but higher carbon content.

Direct Casting Methods

Because of the large investment needed to build conventional steelmaking casting and rolling facilities, the focus over the last ten years has been on reducing production costs and simplifying the overall steelmaking process. For the most part, cost savings have been achieved by the progression of casting technology from ingot to continuous casting, which eliminates soaking and breakdown hot rolling of large ingots. The following table compares the continuous cast share (in percent) for the United States, the European Economic Community (EEC), Japan, and the total world:

Country	1981, %	1989, %	1990, %
United States	20.3	63.7	66.2
EEC	42.5	73.7	74.6
Japan	70.7	94.6	95.1
Total world	24.3	44.4	46.8

Source: Wharton Econometric Forecasting Associates

Conventional continuous casting of steels requires the casting of a 150 to 250 mm (6 to 10 in.) thick by 800 to 2200 mm (31 to 86 in.) wide slab that is subsequently rolled down to a thickness of 1.5 to 25 mm (0.05 to 1.0 in.) utilizing a hot strip mill having both four-stand roughing and six- or seven-stand finishing mills (Fig. 3). This process requires a high degree of reduction and the equivalent input of energy.

Fig. 3 Key components of a continuous casting operation. Source: SMS Engineering, Inc.

Direct casting processes are alternatives to conventional slab casting processes. Direct casting processes for steel flat products could be defined as any casting process that produces a casting as close as possible to the final product dimensions of the next processing step. By this definition, direct casting could also be termed near-net shape casting because the final cast dimensions would approach the final product dimensions (Ref 3).

Presently, there are three direct casting alternatives. Listed in increasing order according to how close they come to producing near-net shape dimensions, these processes are (Ref 3):

- Thin slab casting
- Thin strip casting
- Spray casting

The flowcharts in Fig. 4 summarize the key operations involved in these three alternative direct casting processes and compare them with those of a continuous casting process in an integrated steel production facility.

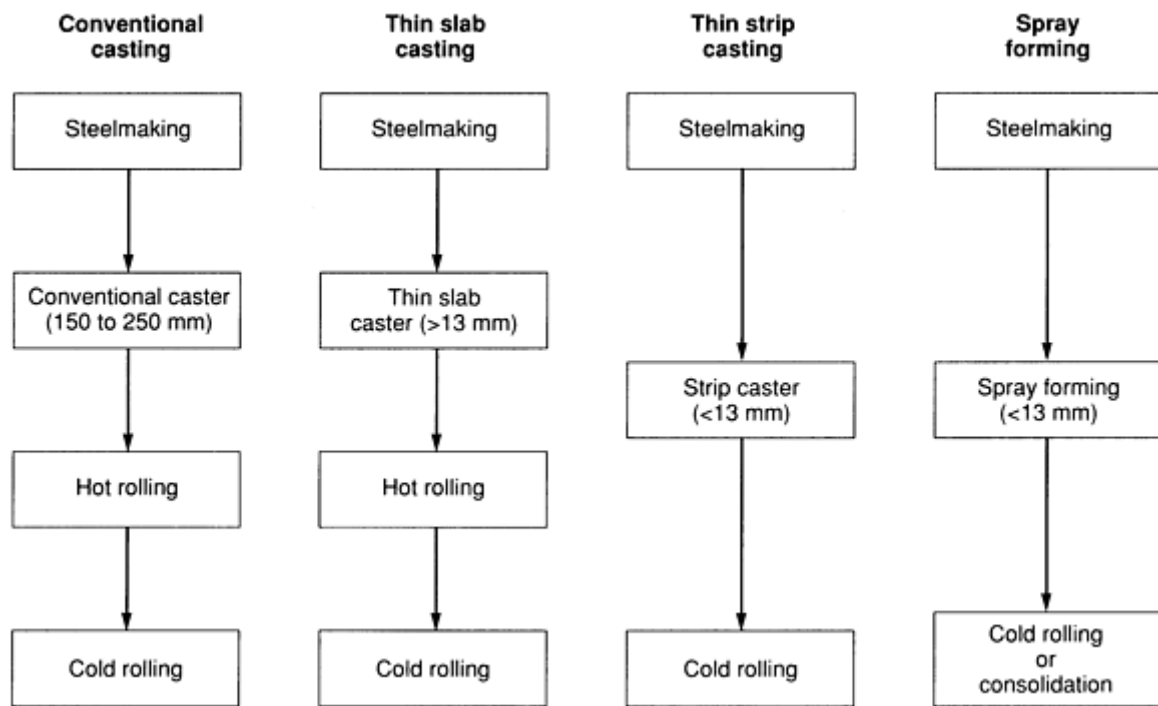

Fig. 4 Flowchart of operations for various strip casting processes. Source: Ref 3

Thin Slab Casting. Of the three direct casting processes listed above, only the thin slab casting process is being used commercially. In thin slab casting, a slab 40 to 60 mm (1.5 to 2.5 in.) is produced. Hot rolling is not completely eliminated in this process, but the amount of reduction necessary to produce strip is greatly reduced. However, the need for a heating furnace and a roughing mill is eliminated (Fig. 5). In addition, thin slab casting yields a finer grain structure and a better finish than that obtained with conventional continuous casting technology.

Fig. 5 Key components of a thin slab casting facility. Compare with Fig. 3. Source: SMS Engineering, Inc.

Table 10 lists some of the countries and specific firms engaged in research and development of thin slab casting worldwide. References 3, 4, 5, 6, and 7 provide detailed information on the start-up of a thin slab casting minimill.

Source: Ref 3

In thin strip casting, a strip that is generally less than 5 mm (0.2 in.) thick is cast. In this process, the most optimistic scenario is that the need for a hot strip mill will be eliminated altogether. As indicated in Table 10, there are three areas of concentration in thin strip casting:

- Single-roll process
- Twin-roll process
- Electromagnetic levitation

Strip casting is expected to be available for commercialization within the next five to ten years if significant advances in control and quality can be achieved. Currently, single-roll casting is closer to commercialization processes than twin-roll processes, especially in the area of stainless steel manufacture. Additional information on thin strip casting can be found in Ref 3.

In spray forming, a liquid metal is atomized and sprayed onto a substrate in an inert atmosphere to form a sheet (Ref 3). Because it eliminates conventional casting and hot rolling processes, spray forming is a true near-net shape casting technology. Compaction after forming is normally necessary to eliminate porosity and to achieve high density. This technology has been applied to the manufacture of rings, tubes, small billets, and pipes for both ferrous and non-ferrous applications. Both centrifugal atomization processes such as controlled spray deposition and gas atomization processes are included in this category (Table 10).

The commercialization of spray casting for strip production is at least five to ten years in the future for bulk steelmaking. In addition, applying this technology to low-carbon aluminum-killed strip may be difficult because of surface quality and yield requirements.

Precoated Steel Sheet

Revised by R. W. Leonard, USS Corporation, Division of USX Corporation

Introduction

STEEL SHEET is often coated in coil form before fabrication either by the steel mills or by specialists known as coil coaters. This prefinished or precoated sheet is ready for fabrication and use without further surface coating. Precoated products yield lower production costs, improved product quality, shorter processing cycles, elimination of production hazards, conservation of energy, minimized ecological problems, and production expansion without a capital expenditure for new buildings and equipment.

Some precautions are necessary with pre-coated sheet. The product must be handled with more care to prevent scratches and damage to the prefinished surface. Metal finishing of damaged areas is more difficult than on uncoated sheet. Fabrication methods are more restrictive, bend radii must be more generous, and welding practices must be carefully chosen.

The basic types of precoating include metallic, pretreated, preprimed, and pre-painted finishing. Metallic coating can be made up to zinc, aluminum, zinc-aluminum alloys, tin, and terne metal. Pretreatment coatings are usually phosphates, and pre-primed finishes can be applied as a variety of organic-type coatings. These can be used as a primed-only coating, or a suitable paint topcoat can be applied. Prepainting consists of applying an organic paint system to steel sheet on a coil coating line either at a mill or at a coil coater. This article will address each of these coating processes. Emphasis will be placed on products that are galvanized by the hot dip process, although much of the discussion is equally applicable to electrogalvanizing and zinc spraying.

Zinc Coatings

Galvanizing is a process for rustproofing iron and steel by the application of a metallic zinc coating. It is applicable to products of nearly all shapes and sizes, ranging from nails, nuts, and bolts to large structural assemblies and steel sheet in coils and cut lengths. Other applications include roofing and siding sheets for buildings, silos, grain bins, heat exchangers, hot water tanks, pipe, culverts, conduits, air conditioner housings, outdoor furniture, and mail boxes. On all steel parts, galvanizing provides long-lasting, economical protection against a wide variety of corrosive elements in the air, water, or soil.

In the United States, more than 9×10^6 Mg (1×10^7 tons) of steel is produced annually by precoating. A large amount of this total is used by the automotive industry for both unexposed and exposed panels--from frames and floor pans to doors, fenders, and hoods (Fig. 1). Typically, 75% of the body, chassis, and power train components of one American automobile manufacturer's 1986 models consisted of galvanized precoated sheet (Fig. 2). Table 1 indicates that a typical 1986 American car utilized nearly 160 kg (350 lb) of zinc-coated steel components in its material composition. As indicated in Table 2, undervehicle test coupons evaluated after 2 years of exposure attest to the benefits of precoated steels in combating corrosion (additional information is available in the article "Corrosion in the Automobile Industry" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*).

Table 1 Use of zinc-coated steel for a typical 1986 model U.S. car

Type	Amount of steel		Amount of zinc	
	kg	lb	kg	lb
One-side galvanized	33.5	74	0.55	1.21
Two-side galvanized	93	205	3.05	6.72
Zincrometal	29.5	65	0.19	0.41
Net total	156	344	3.8	8.34

Metallic zinc is applied to iron and steel by three processes: hot dip galvanizing, electrogalvanizing, and zinc spraying. Most galvanized steel sheet is coated by the hot dip process, although there has been strong growth in electrogalvanizing capacity during the past few years.

Corrosion Resistance. The use of zinc is unique among methods for the corrosion protection of steel. The zinc coating serves a twofold purpose:

- It protects the steel from corrosive attack in most atmospheres, acting as a continuous barrier shield between the steel and the atmosphere
- It acts as a galvanic protector, slowly sacrificing itself in the presence of corrosive elements by continuing to protect the steel even when moderate-sized areas of bare metal have been exposed

This latter ability is possible because zinc is more electrochemically active than steel. This dual nature of zinc coatings is also available with some zinc/aluminum alloy coatings, but zinc coatings clearly offer the most galvanic protection. With most protective coatings that act only as a barrier, rapid attack commences when exposure of the base metal occurs.

The distance over which the galvanic protection of zinc is effective depends on the environment. When completely and continuously wetted, especially by a strong electrolyte (for example, seawater), relatively large areas of exposed steel will be protected as long as any zinc remains. In air, where the electrolyte is only superficially or discontinuously present (such as from dew or rain), smaller areas of bare steel are protected. The order of magnitude of this throwing power is nominally about 3.2 mm ($\frac{1}{8}$ in.), although this can vary significantly with the type of atmosphere. Nevertheless,

galvanized parts exposed outdoors have remained rust free for many years, and the two basic reasons are the sacrificial protection provided by the zinc and the relatively stable zinc carbonate film that forms on the zinc surface to reduce the overall corrosion rate of the zinc coating.

The service life of zinc-coated steel is dependent on the conditions of exposure and on the coating thickness, as illustrated in Fig. 3. Although the coating process used to apply the zinc coating generally does not affect the service life, experience has shown that the corrosion resistance of galvanized coatings in the field cannot be accurately predicted from accelerated laboratory tests. Environmental factors such as atmospheric contaminants (sulfates, chlorides, and so on) and time of wetness have a large influence on the service life of galvanized steel. In polluted areas, such as severe industrial areas, the normally protective zinc carbonate film that forms on the surface of the zinc coating tends to be converted to soluble sulfates that are washed away by rain, thus exposing the zinc to further attack and accelerating the corrosion.

Fig. 3 Service life of zinc-coated steel sheet. Service life is measured in years to the appearance of first significant rusting.

Coating Test and Designations. The thickness (or weight), adhesion, and ductility of a zinc coating can have important effects on its service life and effectiveness against corrosion. Practical tests for these characteristics are described in relevant specifications issued by the American Society for Testing and Materials (ASTM). Tests for coating thickness include microscopic measurement of the cross section, stripping tests in which the coating is removed from a given area (ASTM A 90), electrochemical stripping from a given area (ASTM B 504), and magnetic and electromagnetic methods of measurement (ASTM E 376, A 123, A 754, B 499, and D 1186). Adhesion can be tested and rated by bend

test methods described in ASTM A 525 and A 879. Other adhesion test methods include reverse impact and draw bend test.

Because the service life of a zinc-coated part in a given atmosphere is directly proportional to the thickness of zinc in the coating (Fig. 3), measurement of that amount is very important. The amount of coating is most often measured in terms of weight rather than thickness, usually by the method described in ASTM A 90. Specimens are cut from one or three spots in samples of the sheet, as described in ASTM A 525. These are weighed, the zinc is stripped (dissolved) in an acid solution, and the specimens are reweighed. The weight loss is reported in ounces per square foot of sheet or grams per square meter. When specimens from three spots are checked (triple-spot test), the value of weight loss is the average of the three specimens.

When the weight-loss method is used, the amount of coating measured is the total amount on both sides of the sheet. Ordinarily, the zinc coating is applied to both sides of the sheet. Therefore, a 2 oz/ft² coating has 305 g/m² (1 oz/ft²) on each surface. This 28 g (1 oz) is equivalent to an average thickness of 43 µm (1.7 mils). When zinc-coated sheet is ordered, the minimum amount of coating can be specified as the weight determined by the triple-spot or single-spot test or by coating designations corresponding to these weights (Table 3).

Table 3 Designations and weights of zinc coating on hot dip galvanized sheet

Chromate Passivation. Several types of finishes can be applied to zinc-coated surfaces to provide additional corrosion resistance. The simplest type of finish applicable to fresh zinc surfaces is a chromate passivation treatment. This process is equally suitable for use on hot dip galvanized, electrogalvanized, zinc-sprayed, and zinc-plated articles. Usually, the treatment consists of simply cleaning and dipping the articles in a chromic acid or sodium dichromate solution at about 20 to 30 °C (68 to 86 °F), followed by rinsing in cold fresh water and drying in warm air. The adherent chromate film may have a greenish or greenish-yellow iridescent appearance. Specification ASTM B 201 gives details of tests for measuring the adequacy and effectiveness of the chromate film. Chromate passivation helps prevent staining when galvanized sheet is stored under wet or humid conditions. Therefore, a thin, almost clear chromate or chromate/phosphate passivation film is often applied to the coating on hot dip coating lines.

Painting. The selection of galvanized steel as a material for barns, buildings, roofs, sidings, appliances, and many hardware items is based on the sacrificial protection and the barrier coating afforded the base metal by zinc coating. For additional protection and cosmetic appearance, paint coatings are often applied to the galvanized steel. The performance of the coatings is an important economic factor in the durability of this material (Table 4).

(a) Service life is defined as time to about 5% red rust.

Galvanized steel, both new and weathered, can be painted with a minimum of preparation and with excellent adherence. On hot dip galvanized or zinc-plated steel, it is necessary to use special corrosion-inhibitive primers to prepare the surface before the paint is applied. This is partly because these types of zinc coating are too smooth to provide a mechanical key for the paint or lacquer and partly because the paint appears to react with the unprepared zinc surface in the presence of moisture to weaken the initially formed bond.

Many exposure tests have shown that zinc dust-zinc oxide paints (finely powdered zinc metallic and zinc oxide pigment in an oil or alkyd base) adhere best to galvanized steel surfaces under most conditions. Zinc dust-zinc oxide primers can be used over new or weathered galvanized steel and can be top coated with most oil or latex house paints or alkyd enamels. For the maintenance painting of galvanized steel, one or two coats of a zinc dust-zinc oxide paint are often used alone. The paint can be applied by brushing, rolling, or spraying.

Zinc sheets to be painted should not be treated at the mill with a chromate treatment, although, they may be given a phosphate treatment to improve the adherence of the paint. Zinc-coated sheet steel is often prepainted in coil form by coil coating, is described in the section "Prepainted Sheet" in this article.

Packaging and Storage. Galvanized products in bundles, coils, or stacks of sheets must be protected from moisture, including condensation moisture, until openly exposed to the weather. They must be properly packaged and stored. Otherwise, wet-storage stain, a bulky white deposit that often forms on zinc surfaces stored under wet or humid conditions, may develop.

It is important to examine packages of galvanized products for damage and to take prompt action where cuts, tears, or other damage is evident. If the packaging is damaged or if moisture is present, the product should be dried at once and not repiled until thoroughly dry. Erection of materials should begin as soon as possible after the package arrives at the installation site.

If temporary storage of the galvanized product is absolutely necessary, it should be indoors. Where indoor storage is not possible, intact waterproof bundles can be stored at the site. The package should be slanted so that any condensation will drain out, and it should be stored sufficiently high to allow air circulation beneath and to prevent rising water from entering. The stacks should be thoroughly covered with a waterproof canvas tarpaulin for protection from rain, snow, or condensation. The use of airtight plastic coverings should be avoided. To deter the formation of wet-storage stain, zinc-coated sheet can be purchased with a mill-applied chromate or chromate/phosphate film. Various proprietary mixtures are available.

Hot dip galvanizing is a process in which an adherent, protective coating of zinc and iron-zinc alloys is developed on the surfaces of iron and steel products by immersing them in a bath of molten zinc. Most zinc coated steel is processed by hot dip galvanizing.

One method of hot dip galvanizing is the batch process, which is used for fabricated steel items such as structurals or pipe. This method involves cleaning the steel articles, applying a flux to the surfaces, and immersing them in a molten bath of zinc for varying time periods to develop a thick alloyed zinc coating.

The most common form of hot dip galvanizing for steel sheet is done on a continuous galvanizing line. Coiled sheet is fed from pay-off reels through flatteners. It is then cleaned, bright annealed, and passed through the coating bath. After leaving the coating bath, the coating thickness is controlled by an air knife or steel rolls. The sheet is then cooled and recoiled or cut into lengths. The hot dip process normally coats both sides of the sheet. However, hot dip galvanized sheets can be coated on one side only for special uses, such as automotive exposed panels, by the use of special coating techniques. One-side coated sheet produced by the hot dip process is not commonly available. Continuous coating lines have to be specially modified to make one-side coated product.

A typical hot dip galvanized coating produced by the batch process consists of a series of layers (Fig. 4). Starting from the base steel at the bottom of the coating, each successive layer contains a higher proportion of zinc until the outer layer, which is relatively pure zinc, is reached. There is, therefore, no real line of demarcation between the iron and zinc, but a gradual transition through the series of iron-zinc alloys that provide a powerful bond between the base metal and the coating. These layers are identified in Table 5. The structure of the coating (the number and extent of the alloy layers) and its thickness depend on the composition and physical condition of the steel being treated as well as on a number of factors within the control of the galvanizer.

Table 5 Properties of alloy layers of hot dip galvanized steels

Layer	Alloy	Iron, %	Melting point		Crystal structure	Diamond pyramid microhardness	Alloy characteristics
			°C	°F			
Eta (η)	Zinc	0.03	419	787	Hexagonal	70-72	Soft, ductile
Zeta (ζ)	FeZn_{13}	5.7-6.3	530	986	Monoclinic	175-185	Hard, brittle
Delta (δ)	FeZn_7	7.0-11.0	530-670	986-1238	Hexagonal	240-300	Ductile
Gamma (Γ)	$\text{Fe}_3\text{Zn}_{10}$	20.0-27.0	670-780	1238-1436	Cubic	...	Thin, hard, brittle

Fig. 4 Photomicrograph of a typical hot dip galvanized coating. The molten zinc is interlocked into the steel by the alloy reaction, which forms zinc-iron layers and creates a metallurgical bond. 250×

The ratio of the total thickness of the alloy layers to that of the outer zinc coating is affected by varying the time of immersion and the speed of withdrawal of the work from the molten zinc bath. The rate of cooling of the steel after withdrawal is another factor to be considered; rapid cooling gives small spangle size.

Sheet galvanizers operating continuous strip processes usually suppress the formation of alloy layers by adding 0.1 to 0.2% Al to the bath; this increases the ductility of the coating, thus rendering the sheet more amenable to fabrication (Fig. 5). Other elements can be added to galvanizing baths to improve the characteristics and appearance of the coating. Lead and antimony give rise to well-defined spangle effects.

Fig. 5 Microstructure of continuously galvanized steel. In continuous hot dip galvanizing, the formation of various iron-zinc alloy layers is suppressed by the addition of 0.1 to 0.2% Al.

During batch galvanizing, the zinc-iron alloy portion of the coating will represent 50 to 60% of the total coating thickness. However, certain combinations of elements may result in a coating that is either completely or almost completely alloyed. Visually, the zinc-iron alloy coating will have a gray, matte appearance because of the absence of the free-zinc layer. The free-zinc layer imparts the typical bright finish to a galvanized coating. Because of the greater percentage of the zinc-iron alloy present in the coating, the alloy-type coating may have a lower adherence than the regular galvanized coating.

The corrosion resistance of the zinc-iron and free zinc coating types is equal for all practical purposes. Steels containing carbon below 0.25%, phosphorus below 0.05%, and manganese below 1.35% (either individually or in combination) will normally develop regular galvanized coatings when conventional galvanizing techniques are used and when silicon is 0.05% or less or ranges between 0.15 and 0.3%. Fabricators and consumers should be aware that a gray matte appearance may occur in batch galvanizing if silicon content exceeds 0.06%. This matte appearance does not reduce the long-term atmospheric corrosion protection of the galvanized coating.

Galvanized coatings on sheet products that are intended to be painted are frequently given treatments to make the spangle less obvious so that it does not show through the paint. A flat spangle without relief (suppressed spangle) can be obtained by small additions of antimony to the molten bath; smaller grain size (minimized spangle) can be produced by spraying the molten zinc with zinc dust, steam, air, or water just before it freezes. Finer grains are less visible through the paint and have narrower and smaller fractures on bending, often permitting the paint to bridge the gap and provide increased protection.

Galvanized steel sheet can be temper rolled to flatten surface irregularities such as dross and grain boundaries, thus providing an extra smooth surface more suitable for painting where critical surface requirements exist. At the galvanizing mill, galvanized steel sheet can be given a thermal treatment after coating, which converts all the free zinc to zinc-iron alloy, thus providing a spangle-free surface that is more suitable for painting. It can be painted without pretreatment (but not with all paints). As an added benefit, there is no spangle to show through the paint. However, the zinc-iron alloy coating is somewhat brittle and tends to powder if severely bent in fabrication.

Table 6 lists the seven ASTM specifications that cover hot dip galvanized steel sheet products. The general requirements for the products covered in these specifications are described in ASTM A 525. Included in this specification are the bend test requirements given in Table 7, but not included in these bend test requirements are those for structural (physical) quality sheet, which are given in Table 8.

Table 6 ASTM specifications for hot dip galvanized steel sheet

General requirements are given in A 525.

Specification	Application or quality
A 361	Sheet for roofing and siding
A 444	Sheet for culverts and underdrains
A 446	Structural (physical) quality sheet
A 526	Commercial quality sheet
A 527	Lock-forming quality sheet
A 528	Drawing quality sheet
A 642	Drawing quality, special killed sheet

G 01	$1\frac{1}{2}t$	$2t$	$2\frac{1}{2}t$
Base metal	$1\frac{1}{2}t$	$2t$	$2\frac{1}{2}t$

- (a) Value listed is the minimum diameter of rod (or mandrel), in multiples of the galvanized sheet thickness (t), around which the sheet can be 180° in any direction at room temperature without flaking of the coating, or cracking of the base metal, on the outside of the bend. There are no bend

test requirements for coatings and base metal of grades D, E, and F.

The typical mechanical properties of commercial quality (CQ), drawing quality (DQ), and drawing quality, special killed (DQSK) hot dip galvanized steel sheet are listed in Table 9. Commercial quality sheet is satisfactory for applications requiring bending and moderate drawing. Drawing quality sheet has better ductility and uniformity than commercial quality and is excellent for ordinary drawing applications. Drawing quality, special killed sheet is superior to drawing quality and is excellent for applications requiring severe drawing. When higher strength is required, structural quality (SQ) sheet, also called physical quality (PQ) sheet, can be specified, although at some sacrifice in ductility (compare Tables 7 and 8). The minimum mechanical properties of structural quality sheet are presented in Table 10. Additional information is available in the article "Hot Dip Coatings in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

(a) When the hardness value is 85 HRB or higher, no tensile test is required.

Electrogalvanizing. Very thin formable zinc coatings ideally suited for deep drawing or painting can be obtained on steel products by electrogalvanizing. Zinc is electrodeposited on a variety of mill products: sheet, wire, and, in some cases, pipe. Electrogalvanizing the sheet and wire in coil form produces a thin, uniform coating of pure zinc with excellent adherence. The coating is smooth, readily prepared for painting by phosphatizing, and free of the characteristics spangles of hot dip zinc coatings. Electrogalvanizing can be used where a fine surface finish is needed. The appearance of the coating can be varied by additives and special treatments in the plating bath.

Electrodeposited zinc coatings are simpler in structure than hot dip galvanized coatings. They are composed of pure zinc, have a homogeneous structure, and are highly adherent. These coatings are not generally as thick as those produced by hot dip galvanizing. Electrogalvanized coating weights as high as 100 g/m² (0.3 oz/ft²) have been applied to one or both sides of steel sheet. The normal ranges of coating weights available are listed in ASTM Specifications A 591 and A 879. The coating thicknesses listed in A 591 are typically used when the application does not subject the steel sheet to very corrosive conditions or when the sheet is intended for painting. For more severe corrosion conditions, such as the need to protect cars from road salts and entrapped moisture, heavier coatings in the ranges listed in A 879 are used. These coating weights are applied to the steel sheets used for most body panels.

Electrodeposited zinc is considered to adhere to steel as well as any metallic coating. Because of the excellent adhesion of electrodeposited zinc, electrogalvanized coils of steel sheet and wire have good working properties, and the coating remains intact after severe deformation. Good adhesion depends on very close physical conformity of the coating with the base metal. Therefore, particular care must be taken during initial cleaning. Electrodeposition also affords a means of applying zinc coatings to finished parts that cannot be predipped. It is especially useful where a high processing temperature could damage the part. One advantage of electrodeposition is that it can be done cold and therefore does not change the mechanical properties of the steel.

Zincrometal is also used for outer body panels in automobiles. First introduced in 1972, Zincrometal is a coil coated product consisting of a mixed-oxide underlayer containing metallic zinc particles and a zinc-rich organic (epoxy) topcoat. It is weldable, formable, paintable, and compatible with commonly used adhesives. Zincrometal is primarily used in one-side applications to protect against inside-out corrosion. The corrosion resistance of Zincrometal is not as good as that of hot dip galvanized steels (Ref 1), and its use is declining substantially as more electrogalvanized steels and other types of coatings are employed.

Zinc alloy coated steels have also been developed. Coatings include zinc-iron (15 to 80% Fe) and zinc-nickel (10 to 14% Ni) alloys. These coatings are applied by electrodeposition. Zinc-iron coatings offer excellent corrosion resistance and weldability. Zinc-nickel coatings are more corrosion resistant than pure zinc coatings, but problems include brittleness from residual stresses and the fact that the coating is not completely sacrificial, as is a pure zinc coating. This can lead to accelerated corrosion of the steel substrate if the coating is damaged (Ref 5).

Multilayer coatings that take advantage of the properties of each layer have been developed in Europe. An example of this is Zincrox, a zinc-chromium-chromium oxide coating (Ref 5). The CrO_x top layer of this coating acts as a barrier to perforation and provides excellent paint adhesion and weldability (Ref 5).

Another relatively new development in zinc alloy coatings is Galfan, a Zn-5Al-mischmetal alloy coating applied by hot dipping. Applications in the United States are limited, but European automakers have used Galfan in such applications as brake servo housings, headlight reflectors and frames, and universal joint shrouds (Ref 6). Galfan is also being considered for oil pans, and heavily formed unexposed body panels. Detailed information is available in the article "Electroplated Coatings" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Zinc spraying consists of projecting atomized particles of molten zinc onto a prepared surface. Three types of spraying pistols are in commercial use: the molten metal pistol, the powder pistol, and the wire pistol. The sprayed coating is slightly rough and slightly porous; the specific gravity of a typical coating is approximately 6.35, compared to 7.1 for cast zinc. This slight porosity does not affect the protective value of the coating, because zinc is anodic to steel. The zinc corrosion products that form during service fill the pores of the coating, giving a solid appearance. The slight roughness of the surface makes it an ideal base for paint, when properly pretreated.

On-site spraying can be performed on finished parts of almost any shape or size. When applied to finished articles, welds, ends and rivets receive adequate coverage. Moreover, it is the only satisfactory method of depositing unusually thick zinc coatings (≥ 0.25 mm, or 0.01 in.)

Aluminum Coatings

Aluminized (aluminum-coated) steel sheet is used for applications where heat resistance, heat reflectivity, or barrier-layer resistance to corrosion is required. Aluminum coating of steel sheet is done on continuous lines similar to those used for hot dip galvanizing of steel sheet. Cold-rolled steel sheet is hot dipped into molten aluminum or an aluminum alloy containing 5 to 10% Si. The coating consists of two layers, the exterior layer of either pure aluminum or aluminum-silicon alloy and the steel base metal, with an aluminum-iron-silicon alloy layer in between. The thickness of this alloy can significantly affect the ductility, adhesion, uniformity, smoothness, and appearance of the surface and is controlled for optimum properties.

Aluminum-coated sheet steel combines the desirable properties of aluminum and steel. Steel has a greater load-bearing capacity, having a modulus of elasticity of about three times that of unalloyed aluminum. The thermal expansion of steel is approximately half as much as that of aluminum. The aluminum coating offers corrosion resistance, resistance to heat and oxidation, and thermal reflectivity. Typical applications are:

- Automotive mufflers and related components
- Catalytic converter heat shields
- Drying and baking ovens
- Industrial heating equipment
- Fireplaces
- Home incinerators and furnaces
- Fire and garage doors
- Kitchen and laundry appliances
- Metal buildings
- Agricultural equipment
- Silo roofs
- Playground equipment
- Outdoor furniture
- Signs, masts, and lighting fixtures
- Containers and wrappers

Coating Weight. Aluminum coatings on steel sheet are designated according to total coating weight on both surfaces in ounces per square foot of sheet, as indicated in Table 11. These coating categories are listed in ASTM Specification A 463. Type 1, Light Coating, is recommended for drawing applications and when welding is a significant portion of the fabrication. Type 1, Regular or Commercial, has approximately a 25 μm (1 mil) thick coating on each surface (Fig. 6a). It is designated for applications requiring excellent heat resistance. Type 2 has a coating approximately 50 μm (2 mil) thick on each side (Fig. 6b). It is frequently used for atmospheric corrosion resistance. Coating weight on specimens from aluminum-coated sheet is determined by the test method in ASTM A 428. Figure 7 demonstrates how a typical rear suspension of a front-wheel drive vehicle utilizes type 1 aluminized steel components having a coating of Al-9Si-3Fe in conjunction with galvanized front pivot hangers, mounting brackets, and braces.

Base Metal and Formability. Aluminum coating can be applied to CQ, DQ, or DQSK steel sheet, depending on the severity of the forming or drawing required. Only moderate forming and drawing are recommended for aluminized steel

sheet, but there are numerous intricate components for heating, combustion, and other equipment being produced. Shallow crazing (hairline cracks) may occur in the coating if the bending and forming are too severe. To eliminate crazing, the radius of the bend should be increased. If the crazing is deep enough to expose the steel to the atmosphere during service, staining may occur. These stains generally have minimal effect on the serviceability of the product, because the corrosion stops at the crazed area after a relatively short exposure period. However, if water collects and does not drain off, corrosion products are dissolved and corrosion continues.

The mechanical properties of hot dip aluminized steel sheet are essentially the same as those of hot dip galvanized steel sheet (Table 9). When high strength is required, SQ aluminized steel sheet may be specified, although at some sacrifice in ductility.

Corrosion Resistance. The value of aluminum as a protective coating for steel sheet lies principally in its inherent corrosion resistance. In most environments, the long-term corrosion rate of aluminum is only about 15 to 25% that of zinc. Generally, the protective value of an aluminum coating on steel is a function of coating thickness. The coating tends to remain intact and therefore provides long-term protection.

Aluminum coatings do not provide sacrificial protection in most environments, particularly in atmospheric exposure. This is because a protective oxide film forms on the coating, which tends to passivate the aluminum and retard sacrificial protection. If the oxide film is destroyed, the aluminum will provide sacrificial protection to the base metal. In marine or salt-laden environments, the aluminum coating will protect sacrificially wherever chlorides destroy the surface oxide film.

Although staining or light rusting of the steel may occur at cut edges or crazing may occur where the aluminum does not protect, this action diminishes with further exposure time because of the self-sealing action of corrosion products. However, if insufficient slope or drainage permits water to pond or remain instead of running off freely, the corrosion products are dissolved and rusting will continue.

Heat Resistance. Aluminum-coated sheet steel has excellent resistance to high-temperature oxidation. At surface temperatures below about 510 °C (950 °F), the aluminum coating protects the steel base metal against oxidation without discoloration. Between 510 and 675 °C (950 and 1250 °F), the coating provides protection to the steel, but some darkening may result from the formation of aluminum-iron-silicon alloy. The alloy is extremely heat resistant, but upon long exposure at temperatures above 675 °C (1250 °F), the coating may become brittle and spall because of a different coefficient of expansion from that of the steel.

Because of their good resistance to scaling, combined with the structural strength of the steel base metal, type 1 coatings are used in automotive exhaust systems, heat exchangers, ovens, furnaces, flues, and tubing. The higher strength of the steel base metal, which melts at 1580 °C (2876 °F), enables steel sheet coated with either type 1 or type 2 coatings to perform for a longer time than aluminum alone in the event of fire.

Heat Reflection. The thermal reflectivity of aluminum-coated steel sheet is comparable to that of aluminum sheet. It is superior to galvanized steel sheet after a relatively short exposure time. All three sheet materials have thermal reflectivity of approximately 90% before exposure. However, after a few years, the value for galvanized steel decreases more than that for aluminized steel. Aluminum and aluminum-coated steel sheet retain 50 to 60% of their heat reflectivity. This is advantageous where heat must be confined, diverted, or excluded, as in heat transfer applications. When used for roofing and siding, aluminum-coated sheet keeps buildings cooler in summer and warmer in winter.

Weldability. Aluminum-coated steel sheet can be joined by electric resistance welding (spot welding or seam welding). It can also be metal arc welded, flash welded, or oxyacetylene welded. Thorough removal of grease, oil, paint, and dirt followed by wire brushing is recommended before joining. Special fluxes are required for metal arc and oxyacetylene welding. During spot welding, electrodes tend to pick up aluminum, and the tips must be dressed more frequently than during spot welding of uncoated steel. Also, higher current density is required.

Painting is generally unnecessary, but aluminum-coated sheet steel can be painted similarly to aluminum sheets. This includes removal of oil or grease and treatment with a phosphate, chromate, or proprietary wash-type chemical before painting.

Handling and Storage. The coating on aluminized steel sheet is soft, and care should be taken to avoid scratching and abrasion of the soft coating, which will mar the appearance and allow staining if the coating is removed. Wet-storage stains develop on aluminum-coated steel sheet that is continuously exposed to moisture. The sheet should be inspected for

entrapped moisture when received and then stored indoors in a warm, dry place. Some added protection can be obtained by ordering the sheet oiled or chemically treated for resistance to wet-storage stain.

Aluminum-Zinc Alloy Coatings

In recent years, the desire and need to improve the corrosion resistance of galvanized coatings while retaining sacrificial galvanic corrosion behavior at sheared edges, and so on, have led to the commercial development of two types of hot dip aluminum-zinc alloy coatings. One type consists of about 55% Al and 45% Zn; the other type, zinc plus 5% Al. Both coating types contain small amounts of other alloying elements to improve wettability and/or coating adhesion during forming. Descriptions of these products are contained in ASTM A 792 (55Al-45Zn coating) and A 875 (Zn-5Al coating). These specifications include the general requirements, the coating categories available, and the product types that are available.

The 55% Al coating has been produced worldwide by a number of steel companies for more than 10 years. Its primary use is for preengineered metal buildings, especially roofing. In most environments, this coating has been found to have two to four times the corrosion resistance of galvanized coatings while retaining an adequate level of galvanic protection to minimize the tendency toward rust staining at edges and other breaks in the coating. Figure 8 illustrates the corrosion resistance of 55Al-Zn-coated steel exposed to four atmospheres. The coated sheet is available in similar grades (CQ, DQ, high strength, and so on) as hot dip galvanized and can be subjected to similar types of forming. It can also be painted either by coil-line painting methods or postpainting after fabrication.

Fig. 8 Coating thickness loss of 55Al-Zn-coated steel in four atmospheres. Source: Ref 7

The coating microstructure consists of an aluminum-iron intermetallic alloy bond between the steel and outer coating-metal layer (Fig. 9). This outer coating layer has a duplex microstructure, a matrix phase of an aluminum-rich composition, and a zinc-rich interdendritic phase. This zinc-rich phase corrodes preferentially to provide the galvanic corrosion protection. The coating contains about 2% Si, which is present in the microstructure as an elemental silicon phase. The silicon is added only to inhibit growth of the alloy layer during the hot dip coating operation.

Fig. 9 Microstructure of an aluminum-zinc coated sheet. Etched with Amyl nital. 500×

Although this 55% Al coating is primarily used for metal-building applications, there are a variety of other applications, including appliances and automotive parts. It offers a level of heat-oxidation resistance intermediate between galvanized and aluminized coatings.

The Zn-5Al coating is also produced worldwide, but it is not as commonly available as the 55% Al coating. Its primary attribute is improved coating ductility compared to hot dip galvanized coatings.

This feature, along with a somewhat improved corrosion resistance, makes this coated-sheet product attractive for deep-drawn parts. Also, for prepainted sheets such as roll-formed metal-building panels, the improved coating ductility minimizes the tendency toward cracking of the paint along tension bends.

The Zn-5Al coated sheet is also available in similar grades (CQ, DQ, and so on) as hot dip galvanized. It is readily paintable, including coil-line prepainting.

Both types of aluminum-zinc coating have features that make them more attractive than galvanized for certain applications. Selection of either one should be based on consideration of the desired attributes and differences in fabricability, weldability, paintability, and so on, compared to the other coatings available.

Tin Coatings

Tin coatings are applied to steel sheet by electrolytic deposition or by immersion in a molten bath of tin (hot dip process). Hot dip tin coatings provide a nontoxic, protective, and decorative coating for food-handling, packaging, and dairy equipment, and they facilitate the soldering of components used in electronic and electrical equipment. In the United States, hot dip tin coating has been replaced by electrolytic tin coating.

Electrolytic tin coated steel sheet is used where solderability, appearance, or corrosion resistance under certain conditions is important, as in electronic equipment, food-handling and processing equipment, and laboratory clamps. It is generally

produced with a matte finish formed by applying the coating to base metal sheet called black plate, which has a dull surface texture, and by leaving the coating unmelted. It can also be produced with a bright finish by applying the coating to base metal having a smooth surface texture and then melting the coating. Electrolytic tin coated sheet is usually produced in nominal thicknesses from 0.38 to 0.84 mm (0.015 to 0.033 in.) and in widths from 305 to 915 mm (12 to 36 in.).

Electrolytic tin coated steel sheet can be specified to one of the five coating-weight designations listed in Table 12. The coating weight is the total amount of tin on both surfaces, expressed in ounces per square foot of sheet area. Electrolytic coatings can be applied to CQ, DQ, or DQSK steel sheet, depending on the severity of the forming or drawing required. They can also be applied to SQ steel sheet when higher strength is required. Electrolytic tin coated steel sheet is covered in ASTM A 599. The mechanical properties of the steel sheet are unchanged by the electrolytic tin coating process.

125	18.3	0.060	13.8	0.045

(a) Total weight on both sides of sheet per unit area of sheet.

Terne Coatings

Long terne steel sheet is carbon steel sheet continuously coated by the hot dip process with terne metal (lead with 3 to 15 wt% Sn). This coated sheet is duller in appearance than tin-coated sheet, hence the name (terne) from the French, which means dull or tarnished. The smooth, dull coating gives the sheet corrosion resistance, formability, excellent solderability, and paintability. The term long terne is used to describe terne-coated sheet, while short terne is used for terne-coated plate. Short terne, also called terneplate, is no longer produced in the United States.

Because of its unusual properties, long terne sheet has been adapted to a wide variety of applications. Its greatest use is in automotive gasoline tanks. Its excellent lubricity during forming, solderability and special corrosion resistance make the produce well suited for this application. Other typical applications include:

- Automotive parts, such as air conditioners, air filters, cylinder head covers, distributor tubes, oil filters, oil pans, radiator parts, and valve rocker arm covers
- Electronic chassis and parts for radios, tape recorders, and television sets
- File drawer tracks

- Fire doors and frames
- Furnace and heating equipment parts
- Railroad switch lamps
- Small fuel tanks for lawn mowers, power saws, tractors, and outboard motors

Long terne sheet is often produced to ASTM A 308. The coatings are designated according to total coating weight on both surfaces in ounces per square foot of sheet area, as indicated in Table 13. For applications requiring good formability, the coating is applied over CQ, DQ, or DQSK low-carbon steel sheet. The terne coating acts as a lubricant and facilitates forming, and the strong bond of the terne metal allows it to be formed along with the base metal. When higher strength is required, the coating can be applied over SQ low-carbon steel sheet, although there is some sacrifice in ductility. In general, the mechanical properties of hot dip terne-coated steel are similar to those for cold-rolled steel. Terne coatings are applied by a flux-coating process that does not include in-line annealing. Therefore, the mechanical properties are obtained by pre-annealing using cycles comparable to those used for cold-rolled sheet.

Table 13 Designations and weights of lead-tin coating on terne-coated steel sheet

LT85	259	0.85	214	0.70
LT110	336	1.10	275	0.90

(a) Total weight on both sides of sheet per unit area of sheet.

Lead is well known for its excellent corrosion resistance, and terne metal is principally lead, with some tin added to form a tight, intermetallic bond with steel. The excellent corrosion resistance of terne sheet accounts for its wide acceptance as a material for gasoline tanks. However, because lead does not offer galvanic protection to the steel base metal, care must be exercised to avoid scratches and pores in the coating. Small openings may be sealed by corrosion products of iron, lead, and oxygen, but larger ones can corrode in an environment unfavorable to the steel base metal.

Long terne sheet can be readily soldered with noncorrosive fluxes using normal procedures because the sheet is already presoldered. This makes it a good choice for television and radio chassis and gasoline tanks, for which ease of solderability is important. It can also be readily welded by either resistance seam or spot welding methods. However, when the coating is subjected to high temperatures, significant concentrations of lead fumes can be released. Because of the toxicity of lead, the Occupational Safety and Health Administration and similar state agencies have promulgated standards that must be followed when welding, cutting, or brazing metals that contain lead or are coated with lead or lead alloys.

Long terne sheet has excellent paint adherence, which allows it to be painted using conventional systems, but this product is not usually painted. When painting is done, no prior special surface treatment or primer is necessary, except for the removal of ordinary dirt, oil, and grease. Oiled sheet, however, should be thoroughly cleaned to remove the oil.

Long terne sheet is normally furnished dry and requires no special handling. It should be stored indoors in a warm, dry place. Unprotected, outdoor storage of coils or bundles can result in white or gray staining of the terne coating, and if there are pores in the terne coating, rust staining can occur.

Phosphate Coatings

The phosphate coating of iron and steel consists of treatment with a dilute solution of phosphoric acid and other chemicals by which the surface of the metal, reacting chemically with the phosphoric acid, is converted into an integral layer of insoluble crystalline phosphate compound. This layer is less reactive than the metal surface and at the same time is more absorbent of lubricants or paints. Because the coating is an integral part of the surface, it adheres to the base metal tenaciously. The weight and crystalline structure of the coating, as well as the extent of penetration of the coating into the base metal, can be controlled by the method of cleaning before treatment, the method of applying the solution, the duration of treatment, and the changes in the chemical composition of the phosphating solution.

The two types of phosphate coatings in general use are zinc phosphate and iron phosphate. Within each type, chemical composition can be modified to suit various applications.

When zinc phosphate coatings are mill applied to galvanized sheets, the sheets are ready for immediate painting with the many paints readily available from industrial and retail suppliers. The zinc phosphate coated product is often referred to as phosphatized. Minor cleaning with mineral spirits, paint thinner, or naphtha may be necessary to remove fingerprints, oils, or dirt picked up during fabrication or handling. When mill-phosphatized sheets that are to be baked after painting are exposed to humid storage conditions for long periods of time, prebaking for several minutes at 150 °C (300 °F) prior to painting may be required to prevent blistering during baking.

The chief application for iron phosphate coatings is as a paint base for uncoated carbon steel sheet. Such a coating can be applied on coil coating lines.

The greatest tonnage of phosphate-coated steel is low-carbon flat-rolled material, which is used for applications such as sheet metal parts for automobiles and household appliances. Applications of the coatings range from simple protection to prepaint treatments for painted products, such as preengineered building panels and the side and top panels of washing machines, refrigerators, and ranges.

Phosphate coatings require a clean surface. The cleaning stage preceding phosphating removes foreign matter from the surface and makes uniformity of coating possible. This involves removal of oils, greases, and associated dirt by solvent degreasing or alkaline cleaning followed by thorough rinsing. Phosphate coatings are applied by spray, immersion, or roller coating.

A phosphate coating beneath a paint film helps prevent moisture and other corrosives that may penetrate the paint from reaching the metal. This prevents or delays the electrochemical reactions that lead to corrosion or rust. If the paint film sustains scratches or damage that exposes bare metal, the phosphate coating confines corrosion to the exposed metal surface, preventing the corrosion from spreading underneath the paint film. In painting applications, coarse or heavy phosphate coatings may be detrimental; they can absorb too much paint, thus reducing both gloss and adhesion, especially if deformation of the painted sheet steel is involved.

Preprimed Sheet

Primer paint coats are frequently applied to steel sheet at the mill or by a coil coater. Because their purpose is corrosion protection, they contain corrosion-inhibiting substances such as zinc powder, zinc chromate, or other compounds of zinc and/or chromium. Preprimed sheets are especially useful for parts that will have limited access after fabrication, rendering coating difficult. Parts made from preprimed sheet may receive a top coat after fabrication. The mill-applied phosphate coatings described in the previous section can also be considered prepriming treatments.

Formability (Ref 8). Preprimed steel offers advantages in forming metal fabrication through:

- Consistent surface morphology
- Reduced surface friction (reducing the flow over die surfaces) and reduced die wear, especially on the binder surfaces
- Reduced flaking and powdering (requiring less die maintenance), reduced need for metal finishing, and fewer surface defects
- Reduced galling

The painted surface acts as a cushion between substrate and stamping dies, which lessens the need for in-die lubrication and extends the life of the stamping die. The preprimed, prepainted surface can withstand severe forming and stretching. Thus, the need for lubricant is reduced or eliminated. This in turn provides a clean process environment and reduces the need for extensive cleaning along with phosphating and electrocoating.

Zinc Chromate Primers. Zinc chromate pigments are useful as corrosion inhibitors in paint. They are used as after-pickling coatings on steel and in primers. Federal specifications TT-P-57 and TT-P-645 cover zinc chromate paints. Zinc chromate pigments are unique; they are useful as corrosion inhibitors for both ferrous and nonferrous metals.

Zinc-Rich Primers. In recent years, manufacturers have developed various priming paints that will deposit films consisting mainly of metallic zinc that have many properties in common with the zinc coatings applied by hot dip galvanizing, electroplating, metal spraying, or mechanical plating methods. Such films will provide some degree of sacrificial protection to the underlying steel if they contain 92 to 95% metallic zinc in the dry film and if the film is in electrical contact with the steel surface at a sufficient number of points. The type of zinc dust used in protective coatings is a heavy powder, light blue-gray in color, with spherically shaped particles having an average diameter of approximately 4 μm (160 $\mu\text{in.}$). Such powder normally contains 95 to 97% free metallic zinc with a total zinc content exceeding 99%. Many zinc-rich paints are air drying, although oven-curable primers containing a high content of zinc dust are available.

Depending on the nature of the binder, zinc-rich primers are classified as inorganic or organic. The inorganic solvent-base types are derived from organic alkyl silicates, which, upon curing, become totally inorganic. The organic zinc-rich coatings are formed by using zinc dust as a pigment in an organic binder. This binder may be any of the well-known coating vehicles, such as chlorinated rubber or epoxy. The zinc dust must be in sufficient concentration so that the zinc particles are in particle-to-particle contact throughout the film. In this way, zinc provides cathodic protection to the base metal. With the organic binder, there is no chemical reaction with the underlying surface, but the organic vehicle must wet the surface thoroughly to obtain mechanical adhesion.

The inorganic zinc coating forms its film and adheres to the steel surface by quite different means. The chemical activity during coating is quite similar for either water- or solvent-base inorganic binders. Zinc is the principal reactive element in the inorganic systems and is primarily responsible for the development of initial insolubility.

Zinc-rich primers offer a more versatile application of zinc to steel than galvanizing. Large, continuous, complex shapes and fabricated new or existing structures can be easily coated at manufacturing shops or in the field. The performance of zinc-rich primers has earned them a prominent place in the field of corrosion protection coatings. For example, zinc-rich primers are being preapplied to steel sheet as the first coat of a two-coat system for appliance applications such as refrigerator liners. However, the limitations of zinc-rich paints include cost and the required cleanliness of steel surfaces. They must be top coated in severe environments (pH under 6.0 and over 10.5).

The following comparisons should be helpful in selecting the binder system that is most suitable for an application. Inorganics have superior solvent and fuel resistance. They can withstand temperatures to 370 °C (700 °F) and are much easier to clean up after use. Inorganics do not blister upon exposure and are unaffected by weather, sunlight, or wide variations in temperature. They do not chalk, peel, or lose thickness over long periods of time. Also, they are easier to

weld through and have excellent abrasion resistance and surface hardness. Organics use chlorinated rubber, epoxy, vinyl, phenoxy, or other coating vehicles, and the properties of the system are based on the characteristics of the vehicle used.

Organic Composite Coatings

Organic composite coated steels have been developed mainly by Japanese steelmakers in cooperation with automakers in that country, although development is underway in other countries as well. These coil coated products generally employ an electroplated zinc alloy base layer and a chemical conversion coating under a thin organic topcoat containing a high percentage of metal powder (Ref 9, 10, 11). The thinness of the organic topcoat allows for good formability without the risk of damaging the coating.

Figure 10 compares the corrosion resistance of one of these organic composite coated sheet steels to cold-rolled steel and to Zincrometal. Another of these products uses an organic-silicate composite topcoat only about 1 μm (40 $\mu\text{in.}$) thick and has corrosion resistance and weldability superior to that of Zincrometal (Ref 10). A bake-hardenable version of this material has also been developed (Ref 10). Researchers at a third Japanese steel company have developed a bake-hardenable organic composite coated sheet steel with a 0.8 to 1.5 μm (32 to 60 $\mu\text{in.}$) thick organic topcoat. The material possesses corrosion resistance, formability, and weldability equivalent to that of Zincrometal-KII, which uses a 7 μm (280 $\mu\text{in.}$) thick topcoat (Ref 11). Production of these composite-coated materials is increasing in anticipation of increased demand from Japanese automakers.

Fig. 10 Corrosion of heavily worked samples of a composite-coated steel, Zincrometal, and cold-rolled steel in a laboratory cyclic test. Test consisted of 28-min cycles of dipping in 5% saline solution at 40 °C (100 °F), humidifying at 50 °C (120 °F), and drying at 60 °C (140 °F). Source: Ref 9

A similar material has been developed in the United States. This material has an electrodeposited zinc alloy base coat, a mixed intermediate layer of chromium oxide and zinc dust, and an organic topcoat for barrier protection (Ref 12). Figure 11 is a micrograph showing the cross section of the composite-coated steel. In salt spray tests comparing this material to electrodeposited zinc-nickel and Zincrometal, zinc-nickel failed after 216 h, Zincrometal at 480 h, and the composite coating at 960 h (Ref 12). This material was developed to have weldability, formability, and adhesive compatibility similar to that of Zincrometal. Developmental work continuing.

Fig. 11 Scanning electron micrograph of cross section through a composite-coated sheet steel. Source: Ref 12

Organic-Silicate Composite Coatings (Ref 13), Zinc-nickel electroplated steel sheet coated with an organic-silicate composite was developed by a Japanese steel company in an attempt to combine a highly corrosion resistant base zinc-nickel coating with a protective surface layer to prolong the coating life. With a view to forming a thin film with high corrosion resistance, the protective layer was designed as a two-layer protective film structure composed of a chromate film as a lower layer and the organic-silicate composite coating (the composite resin) as an upper layer. This protective film structure improves the corrosion resistance not only by the individual effects of each layer, such as the passivation of chromate film and the excellent corrosion resistance of the composite resin, but also by the suppression of excessive dissolution of Cr^{6+} from the lower chromate film layer by the sealing effect of the upper composite resin layer. This sealing effect sustains the passivation of chromate film more effectively in the corroding environment.

Prepainted Sheet

Prepainted steel sheet is a large and rapidly expanding market. The sheet is coated in coil form in a continuous coil-painting facility. Lower production costs, improved product quality, elimination of production hazards in the shop, customer satisfaction, conservation of energy, elimination of ecological problems, and the ability to expand production without capital expenditure for new buildings and equipment are some of the advantages of prepainted sheet over postpainting. Fabricated parts are readily joined by indirect projection welding, adhesives, tabs, and fasteners. Typical applications of prepainted steel sheet include tool sheds, preengineered buildings, swimming pools, automobiles, lighting

fixtures, baseboard heaters, truck vans, mobile homes, home siding, metal awnings, air conditioners, freezer, refrigerators, ranges, washers, and dryers.

Selection of Paint System. A wide variety of paint systems are available on prepainted sheet. In selecting the proper system for a particular application, the user must consider fabrication requirements, the service life desired, and the service conditions, that will be encountered. For example, in an aggressive environment a plastisol coating may be required. For a deep draw, a vinyl coating should be used instead of a polyester. For resistance to fading in sunlight, a silicone polyester may be suggested instead of a polyester or a vinyl paint.

In the preengineered building field, the paint system must be capable of being roll formed and still perform over the years under a wide variety of conditions without chalking, fading, cracking, or blistering. In the automotive field, the drawing properties of the coating must be considered in addition to corrosion protection from road salts. In the appliance industry, a high-gloss finish that will bend without cracking is important, along with resistance to such materials as detergents, solvents, mustard, ketchup, shoe polish, grape juice, and grease. Other product requirements frequently considered when selecting an appliance paint are color, hardness, adhesion, resistance to abrasion, corrosion, humidity, heat, and pressure marking.

For severe corrosion service and decorative effects, heavier coatings are supplied, often by laminating or bonding a solid film to the metal substrate. Typical applications include buildings, roofing and siding near pickling tanks, chemicals and other corrosive environments, and storm drains and culverts that are subjected to corrosive soils, mine acids, sewage, and abrasion. These culvert coatings can be a thermoplastic coal tar-base laminate 0.3 to 0.5 mm (0.012 to 0.020 in.) thick, or they can be a film of polyvinyl chloride.

Design Considerations. In using prepainted sheet, design should be considered. If necessary, binding radii, location of exposed edges, fastening methods, welding techniques, corner assembly, and other features should be modified to make them compatible with the base metal and paint system. For example, if a polyester paint is applied to bare steel sheet, a minimum bend radius of 3.2 mm ($\frac{1}{8}$ in.) is suggested to minimize cracking and crazing of the paint. If hot dip galvanized sheet is the substrate, of minimum bend radius of 6.4 mm ($\frac{1}{4}$ in.) should be used instead. Otherwise, the zinc coating may crack with sharper bending, and the paint may not be elastic enough to bridge the crack.

Paint is often cured at temperatures as high as 240 °C (465 °F). At the higher paint curing temperatures, the steel sheet may become fully aged and cause yield point elongation to return. The sheet is subject to the formation of stretcher strains during subsequent forming. Normally, return of yield point elongation is not objectionable in these applications. However, the formed part will sometimes be given a critical amount of strain, and strain lines may become visible. Frequently, this problem can be overcome by proper shop practices, particularly if the part has been roll formed. At times, however, it is necessary to use killed steels, which are considered essentially nonaging.

Shop Practices. Because a prepainted surface is composed of an organic material, the abuse that this surface can withstand is less than that of a metal sheet surface. Therefore, prior to using prepainted sheet for the first time, it is advisable to train shop personnel in proper handling practices and to examine shop equipment to eliminate sources of scratches. For example, dies, brake presses, and roll-forming equipment must have highly polished surfaces free of gouges, score marks, and so on. Clearances of the dies must be such that wiping of the paint film is avoided. Similarly, some care is needed when formed parts are put on carts or in containers for transfer from one location to another. It is not acceptable simply to pile one part on top of another. Good housekeeping is important to minimize the source of scratches. Frequent reexamination of shop equipment and parts containers is necessary to minimize scratches. Handling scratches can be refinished by retouching, which is costly and time consuming.

Packaging and Handling. Shop and field conditions should be considered when selecting packaging for prepainted sheet. Transit pickoff and job-site corrosion from entrapped moisture can be serious problems. For preengineered building sheets, for example, packaging after roll forming should include waterproof paper (no plastic wrapping), support sheets to prevent sagging, and pressure boards. Mixing sheets of different lengths in the bundle should be avoided. Once the bundle of formed prepainted sheets arrives at the job site, it should be inspected to determine if the packages are still intact and resistant to the weather.

Wherever possible, sheets should be erected on the day of delivery, or they should be protected from water condensation. Under-roof storage is desirable. However, if this is not possible, the waterproof bundles should be slanted so that any

condensation will drain out. Damaged packages should be opened, inspected, and the sheets separated to allow complete drying. In addition to the prevention of moisture entrapment described above, chips from drilling operations should be brushed away to prevent rust spotting. Prepainted sheets should be installed with corrosion-resistant fasteners. The installation of sheets that are in contact with the soil should be avoided. Oil, grease, fingerprints, and other contaminants should be removed after installation.

Introduction

STEEL PLATE is any flat-rolled steel product more than 200 mm (8 in.) wide and more than 6.0 mm (0.230 in.) thick or more than 1220 mm (48 in.) wide and 4.6 mm (0.180 in.) thick. The majority of mills for rolling steel plate have a working-roll width between 2030 and 5600 mm (80 and 220 in.). Therefore, the width of product normally available ranges from 1520 to 5080 mm (60 to 200 in.). Most steel plate consumed in North America ranges in width from 2030 to 3050 mm (80 to 120 in.) and ranges in thickness from 5 to 200 mm ($\frac{3}{16}$ to 8 in.). Some plate mills, however, have the capability to roll steel more than 640 mm (25 in.) thick.

Steel plate is usually used in the hot-finished condition, but the final rolling temperature can be controlled to improve both strength and toughness. Heat treatment is also used to improve the mechanical properties of some plate.

Steel plate is mainly used in the construction of buildings, bridges, ships, railroad cars, storage tanks, pressure vessels, pipe, large machines, and other heavy structures, for which good formability, weldability, and machinability are required. The impairment of these desirable characteristics with increasing carbon content usually limits the steel to the low-carbon and medium-carbon constructional grades, with the low-carbon grades predominating. Many alloy steels are also produced as plate. In the final structure, however, alloy steel plate is sometimes heat treated to achieve mechanical properties superior to those typical of the hot-finished product.

Steelmaking Practices

Steel plate is produced from continuously cast slabs or individually cast ingots or slabs. Preparing these steel slabs or ingots for subsequent forming into plates may involve requirements regarding deoxidation practices, austenite grain size, and/or secondary melting practices.

Deoxidation Practices. During the steelmaking process, segregation of carbon can occur when carbon reacts with the dissolved oxygen in the molten steel (a reaction that is favored thermodynamically at lower temperatures). Therefore, the practice of controlling dissolved oxygen in the molten metal before and during casting is an important factor in improving the internal soundness and chemical homogeneity of cast steel. Deoxidation is also important in lowering the impact transition temperatures. Deoxidation can be achieved by vacuum processing or by adding deoxidizing elements such as aluminum or silicon.

Steels are classified by their level of deoxidation: killed steel, semikilled steel, capped steel, and rimmed steel. The steel used for plates is usually either killed or semikilled. Semikilled steel is commonly used for casting ingots because it is more economical than killed steel. Continuously cast steels are normally fully killed to assure internal soundness.

Killed steel is fully deoxidized, and from the viewpoint of minimum chemical segregation and uniform mechanical properties, killed steel represents the best quality available. Therefore, killed steel is generally specified when homogeneous structure and internal soundness of the plate are required or when improved low-temperature impact properties are desired. Killed steel can be produced either fine or coarse grained without adversely affecting soundness, surface, or cleanliness. Generally, heavy-gage plate (thicker than 38 mm, or $1\frac{1}{2}$ in.) is produced from killed steel to provide improved internal homogeneity.

Semikilled steel is deoxidized to a lesser extent than killed steel and therefore does not have the same degree of chemical uniformity or freedom from surface imperfections as killed steel. This type of steel is used primarily on lighter-gage plate, for which high reductions from ingot to plate thicknesses minimize the structural and chemical variations found in the as-cast ingot.

Austenitic Grain Size. Steel plate specifications for structural and pressure vessel applications may require a steelmaking process that produces a fine austenitic grain size. When a fine austenitic grain size is specified, grain-refining elements are added during steelmaking.

Aluminum is effective in retarding austenitic grain growth, resulting in improved toughness for heat-treated (normalized or quenched and tempered) steels. Steels used in high-temperature service normally contain only very small quantities of aluminum because aluminum may affect strain-aging characteristics and graphitization. However, the addition of aluminum may be necessary for some high-temperature steels (as well as most low-temperature steels) requiring good toughness. Other grain-refining elements, such as niobium, vanadium, and titanium, are used in high-strength low-alloy (HSLA) steels for grain refinement during rolling (see the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume).

Melting Practices. The steel for plate products can be produced by the following primary steelmaking processes: open hearth, basic oxygen, or electric furnace. In addition, the steel can be further refined by secondary processes such as vacuum degassing or various ladle treatments for deoxidation or desulfurization.

Vacuum degassing is used to remove dissolved oxygen and hydrogen from steel, thus reducing the number and size of indigenous nonmetallic inclusions. It also reduces the likelihood of internal fissures or flakes caused when hydrogen content is higher than desired. A small cost premium is associated with the specification of vacuum degassing.

Desulfurization. By combining steel refining with the addition of ladle desulfurizing agents (for example, calcium or rare earth additions) immediately before casting or teeming, final plate steel sulfur content can be reduced to less than 0.005%. Lower sulfur content improves plate through-thickness properties and impact properties, but adds to the cost of the steel.

Platemaking Practices

As noted earlier, steel plates are produced from either continuous-cast slabs, pressure-cast slabs, or ingots. Steel ingots are typically between 380 and 1140 mm (15 and 45 in.) thick. These ingots first pass through a slabbing mill where they are reduced in thickness to make a slab. The slab is then inspected, and the surface is conditioned by grinding or scarfing to remove surface imperfections, and then reheated in furnaces prior to rolling to final plate thickness. Continuous-cast slabs and pressure-cast slabs are normally heated and rolled to final plate thickness in a single operation. The plate can then be roller leveled and cooled.

Microalloyed HSLA steels can be controlled rolled for grain refinement (see the article "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume). In this case, the reheating temperature is lower than usual, and the rolling practices are designed to impart heavy reductions at relatively low temperatures. This form of thermomechanically controlled processing (TMCP) is used for grain refinement, which results in plates with improved toughness and strength compared to conventional plate rolling. In some plate mills, controlled rolling is followed by accelerated cooling or direct quenching instead of air cooling. Attractive combinations of strength and toughness can be achieved by TMCP.

After cooling, plates are cut to size by shearing or thermal cutting. Following this operation, testing to confirm mechanical properties is customarily performed, and then the material is shipped to the fabricator. Certain plate products, however, require further processing such as heat treatment.

Plate Imperfections

Certain characteristic surface imperfections that can weaken the plate may appear on hot-finished steel; chemical segregation that can alter properties across the section may also be present. Some of these imperfections are discussed below.

Seams are the most common imperfections found in hot-finished steel. These longitudinal cracks on the surface are caused by blowholes and cracks in the original ingot that have been rolled closed, but not welded. For many plate applications, seams are of minor consequence. However, seams are harmful for applications involving heat treating or upsetting or in certain parts subjected to fatigue loading.

Decarburization, a surface condition common to all hot-finished steel, is produced during the heating and rolling operations when atmospheric oxygen reacts with the heated surface, removing carbon. This produces a soft, low-strength

surface, which is often unsatisfactory for applications involving wear or fatigue. For this reason, critical parts or at least critical areas of parts are usually machined to remove this weakened surface.

Segregation. Alloying elements always segregation during the solidification of steel. Elements that are especially prone to segregation are carbon, phosphorus, sulfur, silicon, and manganese. The effect of segregation on mechanical properties and fabricability is insignificant for most plate steel applications. However, segregation may produce difficulties in subsequent operations such as forming, welding, punching, and machining.

Heat Treatment

Although most steel plate is used in the hot-finished condition, the following heat treatments are applied to plate that must meet special requirements.

Normalizing consists of heating the steel above its critical temperature and cooling in air. This refines the grain size and provides improved uniformity of structure and properties of the hot-finished plate.

When toughness requirements are specified for certain thicknesses in some grades of normalized plate, accelerated cooling must be used in lieu of cooling in still air from the normalizing temperature. Such cooling is accomplished by fans to provide air circulation during cooling or by a water spray or dip. Accelerated cooling is used most often in plates with heavy thicknesses to obtain properties comparable to those developed by normalizing material in the lighter thicknesses.

Quenching consists of heating the steel to a suitable austenitizing temperature, holding at that temperature, and quenching in a suitable medium that depends on chemical composition and cross-sectional dimensions. As-quenched steels are hard, high in strength, and brittle. They are almost always tempered before being placed in service.

Tempering consists of reheating the steel to a predetermined temperature below the critical range, then cooling under suitable conditions. This treatment is usually carried out after normalizing or quenching to obtain desired mechanical properties. Those include a balance of strength and toughness to meet the designer's requirements.

Stress relieving consists of heating the steel to a subcritical temperature to release stresses induced by such operations as flattening or other cold working, shearing, or gas cutting. Stress relieving is not intended to significantly modify the microstructure or to obtain desired mechanical properties.

Types of Steel Plate

Steel plate is classified according to composition, mechanical properties, and steel quality. The three general categories of steel plate considered in this article are carbon steel plate, low-alloy plate, and high-strength low-alloy (HSLA) steel plate. These three categories of steel plate are available in the steel plate quality levels given in Table 1. Further discussion on these various quality levels is provided in the section "Steel Plate Quality" in this article.

General Categories

Carbon steel plate is available in all quality levels except aircraft quality (Table 1) and is available in many grades. Generally, carbon steel contains carbon up to about 2% and only residual quantities of other elements except those added for deoxidation, with silicon usually limited to 0.60% and manganese to about 1.65%. The chemical composition requirements of standard carbon steel plate are listed in Table 2. These steels may be suitable for some structural applications when furnished according to ASTM A 830 and A 6. In addition to the carbon steels listed in Table 2, other carbon steel plates are also classified according to more specific requirements in various ASTM specifications (see the section "Steel Plate Quality" in this article).

Table 2 Standard carbon steel plate compositions applicable for structural applications

When silicon is required, the following ranges and limits are commonly used for nonresulfurized carbon steel: 0.10% max, 0.07-0.15%, 0.10-0.20%, 0.15-0.30%, 0.35% max, 0.20-0.40, or 0.30-0.60%.

(a) Maximum

Low-Alloy Steel Plate. Steel is considered to be low-alloy steel when either of the following conditions is met:

- The maximum of the range given for the content of alloying elements exceeds one or more of the following limits: 1.65% Mn, 0.60% Si, and 0.60% Cu
- Any definite range or definite minimum quantity of any of the following elements is specified or required within the limits of the recognized field of constructional alloy steels: aluminum, boron, chromium up to 3.99%, cobalt, niobium, molybdenum, nickel, titanium, tungsten, vanadium, zirconium, or any other alloying element added to obtain the desired alloying effect

Alloying elements are added to hot-finished plates for various reasons, including improved corrosion resistance and/or improved mechanical properties at low or elevated temperatures. Alloying elements are also used to improve the hardenability of quenched and tempered plate.

Low-alloy steels generally require additional care throughout their manufacture. They are more sensitive to thermal and mechanical operations, the control of which is complicated by the varying effects of different chemical compositions. To secure the most satisfactory results, consumers normally consult with steel producers regarding the working, machining, heat treating, or other operations to be employed in fabricating the steel; mechanical operations to be employed in fabricating the steel; mechanical properties to be obtained; and the conditions of service for which the finished articles are intended.

The chemical composition requirements of standard low-alloy steel plate are listed in Table 3. These low-alloy steels may be suitable for some structural applications when furnished according to ASTM A 6 and A 829. The effect of residual alloying elements on the mechanical properties of hot-finished steel plate is discussed in the section "Mechanical Properties" in this article. The effect of alloying elements on the hardenability and mechanical properties of quenched and tempered steels is discussed in the articles "Hardenable Carbon and Low-Alloy Steels" and "High-Strength Structural and High-Strength Low-Alloy Steels" in this Volume.

Table 3 Composition ranges and limits for AISI-SAE standard low-alloy steel plate applicable for structural applications

Boron or lead can be added to these compositions. Small quantities of certain elements not required may be found. These elements are to be considered incidental and are acceptable to the following maximum amounts: copper to 0.35%, nickel to 0.25%, chromium to 0.20%, and molybdenum to 0.06%.

(a) Except as noted, when a single value is shown, it is a maximum limit.

- (b) Choice and amount of other alloying elements added to give the required mechanical properties and atmospheric corrosion resistance are made by the producer and reported in the heat analysis.
- (c) Elements commonly added include silicon, chromium, nickel, vanadium, titanium, and zirconium.
- (d) Limiting values vary with plate thickness.
- (e) For type 1, 0.005-0.05% Nb; for type 2, 0.01-0.15% V; for type 3, 0.05% Nb max + V = (0.02-0.15%); for type 4, N (with V) 0.015% max.
- (f) For plates under 13 mm ($\frac{1}{2}$ in.) thickness, the minimum niobium limit is waived.
- (g) Niobium may be present in the amount of 0.01-0.05%.
- (h) The minimum total aluminum content shall be 0.018% or the vanadium:nitrogen ratio shall be 4:1 minimum.
- (i) Niobium, or vanadium, or both, 0.005% min. When both are added, the total shall be 0.20% max.
- (j) Applicable only when specified.
- (k) 0.05% max Nb may be present.

Steel Plate Quality

Steel quality, as the term applies to steel plate, is indicative of many conditions, such as the degree of internal soundness, relative uniformity of mechanical properties and chemical composition, and relative freedom from injurious surface imperfections. The various types of steel plate quality are indicated in Table 1.

The three main quality descriptors used to describe steel plate are regular quality, structural quality, and pressure vessel quality. Special qualities include cold-drawing quality, cold-pressing quality, cold-flanging quality, and forging quality carbon steel plate, along with drawing quality and aircraft quality alloy steel plate. Quality descriptors that have been used in the past include flange quality and firebox quality carbon and alloy steel plate and marine quality carbon steel plate. However, use of these descriptors has been discontinued in favor of pressure vessel quality.

Regular quality is the most common quality of carbon steel, which is applicable to plates with a maximum carbon content of 0.33%. Plates of this quality are not expected to have the same degree of chemical uniformity, internal soundness, or freedom from surface imperfections that is associated with structural quality or pressure vessel quality plate. Regular quality is usually ordered to standard composition ranges and is not customarily produced to mechanical property requirements. Regular quality is analogous to merchant quality for bars because there are normally no restrictions on deoxidation, grain size, check analysis, or other metallurgical factors. Also, this quality plate can be satisfactorily used for applications similar to those of merchant quality bars, such as those involving mild cold bending, mild hot forming, punching, and welding for noncritical parts of machinery.

Structural quality steel plate is intended for general structural applications such as bridges, buildings, transportation equipment, and machined parts. The various ASTM specifications for structural quality steel plate are given in Table 5. Most of the structural steel plate listed in Table 5 is furnished to both chemical composition limits (Table 6) and mechanical properties (Table 7). However, some structural steel plate (ASTM A 829 and A 830 in Table 5) is produced from the standard steels listed in Tables 2 and 3. These steels can be furnished only according to the chemical

compositions specified by SAE/AISI steel designations. Factors affecting the mechanical properties of hot-finished carbon steel are discussed in the section "Mechanical Properties" in this article.

Table 5 ASTM specifications for structural quality steel plate

General requirements for structural plate are covered in ASTM A 6.

ASTM specification ^(a)	Steel type and condition
Carbon steel	
A 36 ^(b)	Carbon steel shapes, plates, and bars of structural quality
A 131 ^(c)	Structural steel shapes, plates, bars, and rivets for use in ship construction (ordinary strength)
A 283 ^(b)	Low and intermediate tensile strength carbon steel plates
A 284	Low and intermediate tensile strength carbon-silicon steel plates for machine parts and general construction
A 529 ^(d)	Structural steel with 290 MPa (42 ksi) minimum yield point
A 573	Structural quality carbon-manganese-silicon steel plates with improved toughness
A 678	Quenched and tempered carbon and HSLA plates for structural applications
A 709	Carbon and HSLA steel structural shapes, plates, and bars, and quenched and tempered alloy steel for use in bridges
A 827 ^(e)	Carbon steel plates for forging applications
A 830 ^(e)	Structural quality carbon steel plates furnished to chemical requirements
Low-alloy steel	
A 514	Structural quality quenched and tempered alloy steel plates for use in welded bridges and other structures
A 709	See above under "Carbon steel"
A 710	Low-carbon age-hardening Ni-Cu-Cr-Mo-Nb, Ni-Cu-Nb, and Ni-Cu-Mn-No-Nb alloy steel plates, shapes, and bars for general applications.
A 829 ^{(e)(f)}	Structural quality alloy plates specified to chemical composition requirements
HSLA steel	

A 13 ^(c)	Structural steel shapes, plates, bars, and rivets for use in ship construction (higher strength)
A 242	HSLA structural steel shapes, plates, and bars for welded, riveted, or bolted construction
A 441 ^(g)	Mn-V HSLA steel plates, bars, and shapes
A 572	HSLA structural Nb-V steel shapes, plates, sheet piling, and bars for riveted, bolted, or welded construction of bridges, buildings, and other structures
A 588 ^(h)	HSLA structural steel shapes, plates, and bars for welded, riveted, or bolted construction for use in bridges and buildings with atmospheric corrosion resistance approximately two times that of carbon steel with copper
A 633	Normalized HSLA structural steel for welded, riveted, or bolted construction suited for service at low ambient temperatures of -45 °C (-50 °F) or higher
A 656	Hot-rolled HSLA structural steel with improved formability for use in truck frames, brackets, crane booms, rail cars, and similar applications
A 678	See above under "Carbon steel"
A 709	See above under "Carbon steel"
A 808	Hot-rolled HSLA Mn-V-Nb structural steel plate with improved notch toughness
A 852	Quenched and tempered HSLA structural steel plate for welded, riveted, or bolted construction for use in bridges and buildings with atmospheric corrosion resistance approximately two times that of carbon steel with copper
A 871	HSLA structural steel plate in the as-rolled, normalized, or quenched and tempered condition with atmospheric corrosion resistance approximately two times that of carbon steel with copper

(a) Also designated with the suffix "M" when the specification covers metric equivalents.

(b) This specification is also published by the American Society of Mechanical Engineers, which uses the prefix "S" (for example, SA36).

(c) See also Section 43 of the American Bureau of Shipping specifications and MIL-S-22698 (SH).

(d) 13 mm ($\frac{1}{2}$ in.) maximum thickness.

(e) See also Ref 1.

(f) Tensile properties may also be specified when compatible.

(g) Discontinued in 1989 and replaced by A 572.

(h) Minimum yield point 345 MPa (50 ksi) to 100 mm (4 in.). Lower minimum yield points for thicker sections.

A 827	^(e)	(See Table 11.)									
A 830	^(e)	(See Table 2.)									

(a) Note: See Table 4 for the compositions of structural plate made of HSLA steel.

(b) When a single value is shown, it is a maximum limit, except for copper, for which a single value denotes a minimum limit.

(c) Vanadium can be substituted for part or all of the titanium on a one-for-one basis.

(d) Titanium may be present in levels up to 0.06% to protect the boron additions.

(e) Specification covers many AISI/SAE grades and chemistries.

(f) Limiting values vary with plate thickness.

(g) Minimum value applicable only if copper-bearing steel is specified.

(h) Plates over 13 mm ($\frac{1}{2}$ in.) in thickness shall have a minimum manganese content not less than 2.5 times carbon content.

(i) The upper limit of manganese may be exceeded provided $C + 1/6 \text{ Mn}$ does not exceed 0.40% based on heat analysis.

(a) Where a single value is shown, it is a minimum.

(b) Minimum and/or maximum values depend on plate width and/or thickness.

(c) Specification does not specify mechanical properties.

(d) Includes several AISI/SAE grades

Pressure Vessel Plate. Steel plate intended for fabrication into pressure vessels must conform to specifications different from those of similar plate intended for structural applications. The major differences between the two groups of specifications are that pressure vessel plate must meet requirements for notch toughness and has more stringent limits for allowable surface and edge imperfections.

Table 8 lists the various ASTM specifications for pressure vessel steel plate. All of these steel plate specifications are furnished according to both chemical composition limits and mechanical properties.

Table 8 ASTM specifications for pressure vessel quality steel plate

General requirements for pressure vessel plate are covered in ASTM A 20

Specification	Steel type and condition
Carbon steel	
A 285 ^(a)	Carbon steel plates of low or intermediate tensile strength
A 299 ^(a)	Carbon-manganese-silicon steel plates
A 442 ^(b)	Carbon steel plates for applications requiring low transition temperature
A 455 ^(a)	Carbon-manganese steel plates of high tensile strength
A 515 ^(a)	Carbon-silicon steel plates for intermediate-and higher-temperature service
A 516 ^(a)	Carbon steel plates for moderate and lower-temperature service
A 537 ^(a)	Heat-treated carbon-manganese-silicon steel plates
A 562	Titanium-bearing carbon steel plates for glass or diffused metallic coatings
A 612 ^(a)	Carbon steel plates of high tensile strength for moderate-and lower-temperature service
A 662 ^(a)	Carbon-manganese steel plates for moderate-and lower-temperature service

A 724	Quenched and tempered carbon steel plates for layered pressure vessels not subject to postweld heat treatment
A 738 ^(a)	Heat-treated carbon manganese-silicon steel plates for moderate-and lower-temperature service
Low-alloy steel	
A 202 ^(a)	Cr-Mn-Si alloy steel plates
A 203 ^(a)	Nickel alloy steel plates
A 204 ^(a)	Molybdenum alloy steel plates
A 225 ^(a)	Mn-V alloy steel plates
A 302 ^(a)	Mn-Mo and Mn-Mo-Ni alloy steel plates
A 353 ^(a)	Double normalized and tempered 9% Ni alloy steel plates for cryogenic service
A 387 ^(a)	Cr-Mo alloy steel plates for elevated-temperature service
A 517 ^(a)	Quenched and tempered alloy steel plates of high tensile strength
A 533 ^(a)	Quenched and tempered Mn-Mo and Mn-Mo-Ni alloy steel plates
A 542 ^(a)	Quenched and tempered Cr-Mo alloy steel plates
A 543 ^(a)	Quenched and tempered Ni-Cr-Mo alloy steel plates
A 553 ^(a)	Quenched and tempered 8% and 9% Ni alloy steel plates
A 645 ^(a)	Specially heat treated 5% Ni alloy steel plates for low-or cryogenic-temperature service
A 734	Quenched and tempered alloy and HSLA steel plates for low-temperature service
A 735	Low-carbon Mn-Mo-Nb alloy steel plates for moderate-and lower-temperature service
A 736	Age-hardening low-carbon Ni-Cu-Cr-Mo-Nb alloy steel plates
A 782	Quenched and tempered Mn-Cr-Mo-Si-Zr alloy pressure vessel steel plates
A 832	Cr-Mo-V-Ti-B alloy pressure vessel steel plates

A 844	9% Ni alloy pressure vessel steel plates produced by the direct-quenching process
HSLA steel	
A 734	See under "Alloy steel"
A 737 ^(a)	HSLA steel plates for applications requiring high strength and toughness
A 841	Steel pressure vessel plate produced by the thermomechanical control processes

(a) This specification is also published by the American Society of Mechanical Engineers, which adds an "S" in front of the "A" (for example, SA285).

(b) Discontinued in 1991

(c)

The chemical composition limits of pressure vessel steel plate include a maximum phosphorus content of 0.035% and a maximum sulfur content of 0.040% by product analysis. The chemical compositions of various types of pressure vessel steel plate are given in Table 9.

Table 9 ASTM specification of chemical composition for pressure vessel plate made of carbon and low-alloy steel

See Table 4 for the compositions of pressure vessel plate made of HSLA steel. The maximum limits per ASTM A 20 on unspecified elements are 0.40% Cu, 0.40% Ni, 0.30% Cr, 0.12% Mo, 0.03% V, and 0.02% Nb.

(a) When a single value is shown, it is a maximum limit, except where specified as a minimum limit.

(b) Limiting values may vary with plate thickness.

(c) When specified

Mechanical tests of pressure vessel steel plate involve a minimum of one tensile test for each as-rolled plate or a minimum of two tensile tests for quenched and tempered plates. The mechanical property requirements given in ASTM specifications for pressure vessel steel plate are listed in Table 10.

Table 10 ASTM specifications of mechanical properties for pressure vessel plate made of carbon steel, HSLA steel, or low-alloy steel

(a) Where a single value is shown, it is a minimum.

(b) Minimum and/or maximum values depend on plate thickness.

(c) As-rolled class 1 plate is limited to 25 mm (1 in.) thickness.

(d) As-rolled and aged class 2 plate is limited to 25 mm (1 in.) thickness.

Aircraft quality plates are used for important or highly stressed parts of aircraft, missiles, and other applications involving stringent requirements. Plates of this quality require exacting steelmaking, conditioning, and process controls and are generally furnished from electric furnace steels in order to meet the internal cleanliness requirements outlined in

Aerospace Materials Specifications AMS-2301. The primary requirements of this quality are a high degree of internal soundness, good uniformity of chemical composition, good degree of cleanliness, and a fine austenitic grain size. Aircraft quality plates can be supplied in the hot-rolled or thermally treated condition.

Forging quality plates are intended for forging, quenching and tempering, or similar purposes or when uniformity of composition and freedom from injurious imperfections are important (see ASTM A 827). Plates of this quality are produced from killed steel and are ordinarily furnished with the phosphorus content limited to 0.035% maximum and the sulfur content limited to 0.040% maximum by heat analysis. Table 11 lists some AISI/SAE steels suitable for forging quality plate. Plates of this quality can be produced to chemical ranges and limits and mechanical properties. When mechanical properties are specified, two tension tests from each heat are taken from the same locations at tests for structural quality. Factors affecting mechanical properties are discussed in the section "Mechanical Properties" in this article.

Mechanical Properties

Of the various mechanical properties normally determined for steel plate, yield strength is an important design criterion in structural applications. Tensile strength is also an important design consideration in many design codes in the United States, but is useful primarily as an indication of fatigue properties. Yield strength is a design criterion in most design codes when the ratio of yield to tensile strength is less than 0.5. Ductility, as measured by tensile elongation and reduction in area, is seldom in itself a valuable design criterion, but is sometimes used as an indication of toughness and suitability for certain applications.

The mechanical properties of steel plate in the hot-finished condition are influenced by several variables, of which chemical composition is the most influential. Other factors include deoxidation practice, finishing temperature, plate thickness, and the presence of residual elements such as nickel, chromium, and molybdenum. For steels used in the hot-

finished condition (such as plate), carbon content is the single most important factor in determining mechanical properties.

The static tensile properties of the various grades, types, and classes of steel plate covered by ASTM specifications are listed in Tables 7 and 10. It should be noted that some of these values vary with plate thickness and/or width. An example of the variation of tensile strength and elongation with thickness is shown in Fig. 1, which presents the minimum expected values for 0.20% C steel plate from 13 to 125 mm ($\frac{1}{2}$ to 5 in.) thick. Plate under 13 mm ($\frac{1}{2}$ in.) thick would show even slightly higher tensile strength and lower elongation because of the increased amount of hot working during rolling and the faster cooling rates after rolling.

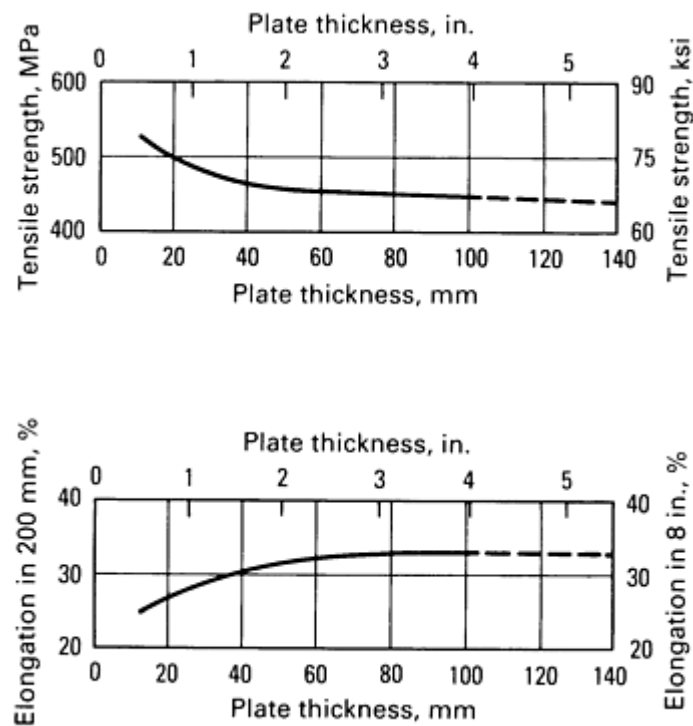

Fig. 1 Effect of thickness on tensile properties of 0.20% C steel plate

The distribution of the tensile properties obtained for a larger number of heats of A 285, A 515, and A 516 steel plate is illustrated in Fig. 2, which also shows the distribution of the carbon and manganese content. The use of the carbon and manganese contents to control mechanical properties is clearly shown in Fig. 2; higher carbon and manganese contents accompany higher yield strengths.

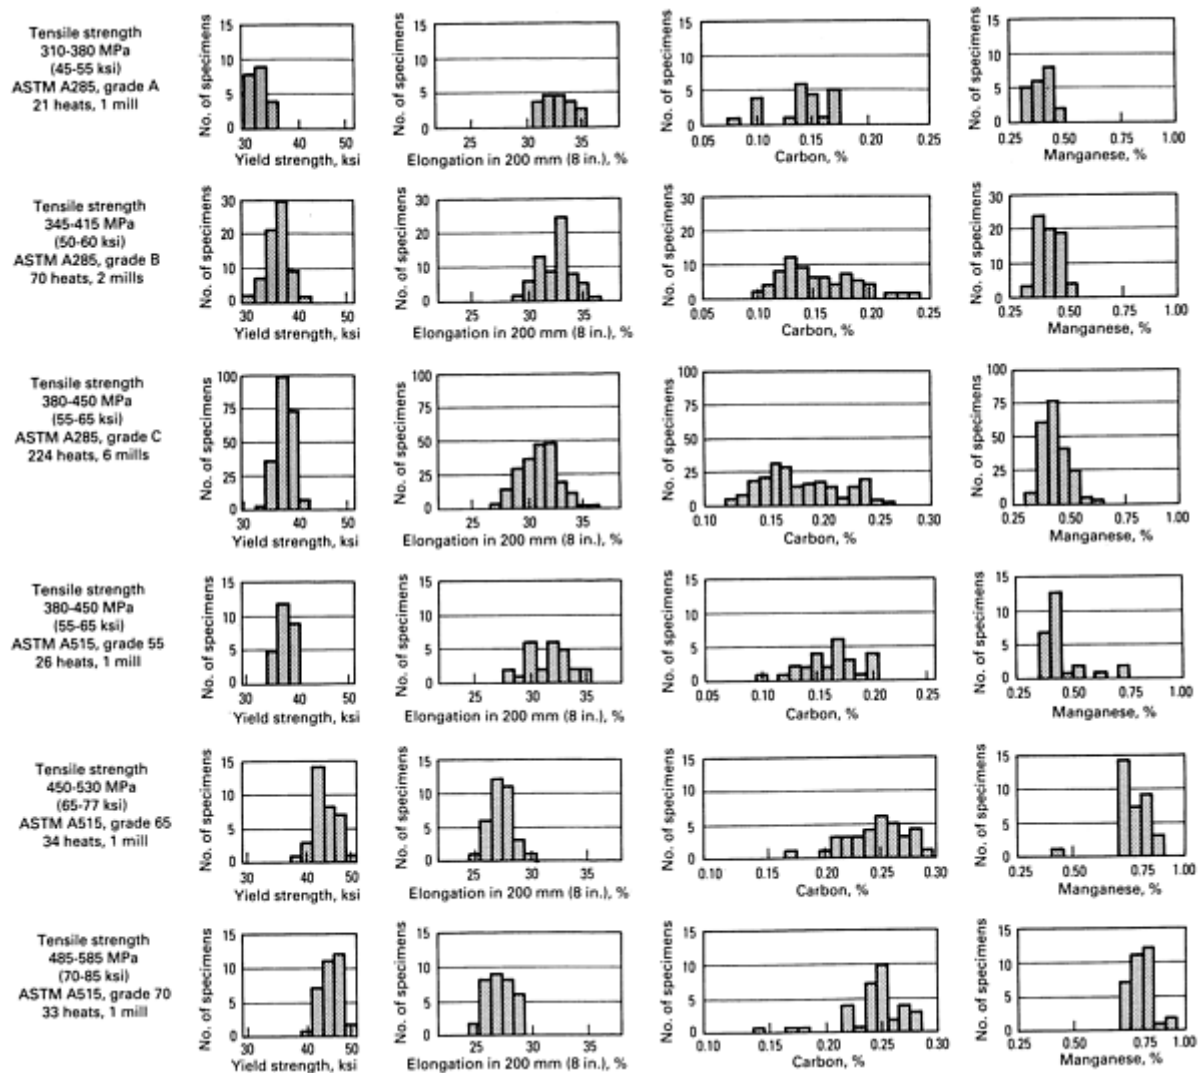

Fig. 2 Distribution of tensile properties and chemical composition of carbon steel plate. Data represent all the as-hot-rolled plate, 6 to 50 mm ($\frac{1}{4}$ to 2 in.) thick, purchased to these specifications by one fabricator during a period of 8 years.

Figure 3 repeats the data in Fig. 2 for the 224 heats of A 285, grade C plate. However, the data are augmented by the individual distributions for the various ranges of plate thickness included in the investigation. When steel is produced to a mechanical property requirement, it is common practice to vary the carbon and manganese to compensate for size influence. The use of higher-than-average carbon (and manganese) content to maintain yield strength as plate thickness increases is evident in Fig. 3.

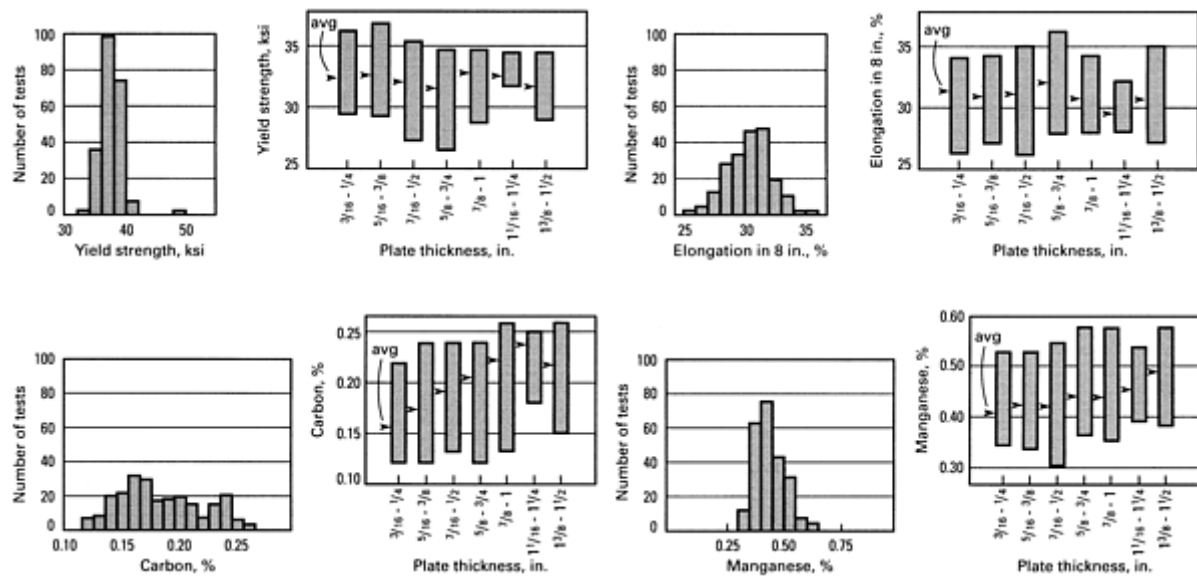

Fig. 3 Distribution of tensile properties and chemical composition of ASTM A 285, grade C, carbon steel plate. Data represent all the as-hot-rolled plate (224 heats from 6 mills) purchased to this specification by one fabricator during a period of 8 years.

The common mechanical properties of hot-finished steel, including plate, reliably related to each other, and this relation is relatively free from influence of composition for most of these properties. Figure 4 shows the relationship between yield strength, elongation, and tensile strength over a wide range of tensile strengths for various hot-rolled carbon steels.

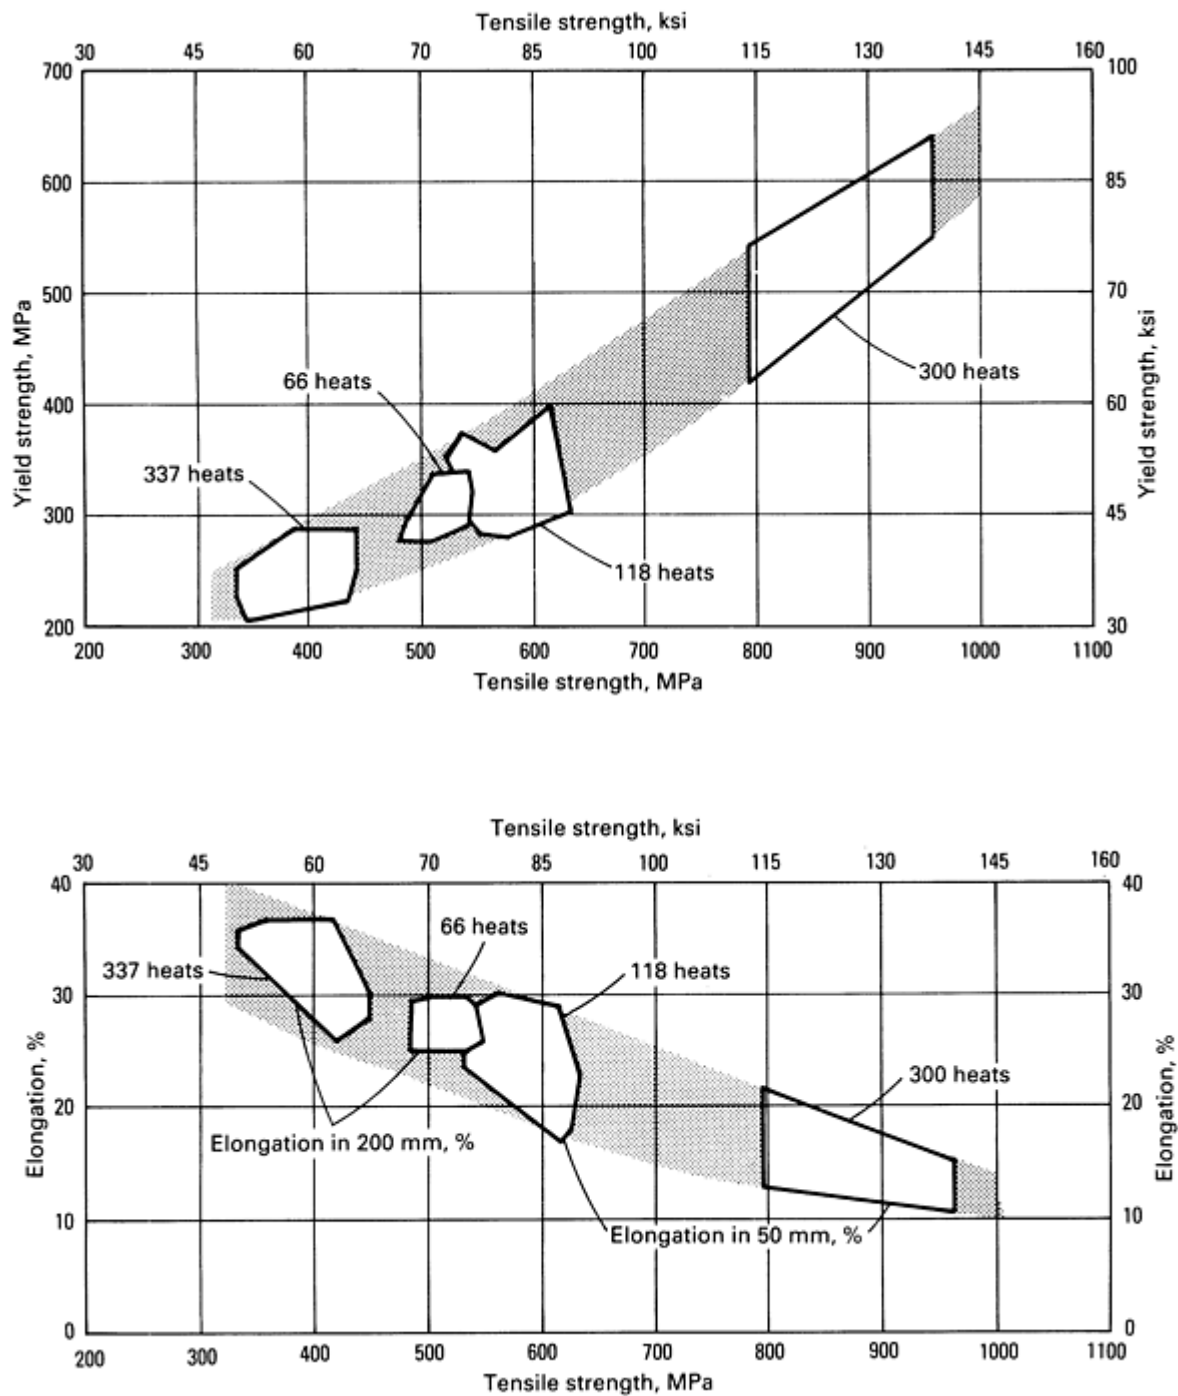

Fig. 4 Relation of tensile properties for hot-rolled carbon steel

Residual alloying elements generally have a minor strengthening effect on hot-finished steels, such as plate. This effect cannot be considered in design because residuals vary greatly among the different steel producing plants. This influence is shown in Fig. 5, which demonstrates that the effect is minor.

Fig. 5 Effect of carbon and amount of residuals on tensile properties of hot-finished carbon steel. Curves marked high residuals represent steel containing 0.06 to 0.12% Ni, 0.06 to 0.13% Cr, and 0.08 to 0.13% Mo. Curves marked low residuals represent steel containing 0.05% Ni max, 0.05% Cr max, and 0.04% Mo max. Total of 58 heats tested

Hardness is a relatively simply test to perform and is closely related to tensile strength, as shown in Fig. 6. A simple hardness test, used in conjunction with the data in Fig. 4, can be used to estimate yield strength, elongation, and tensile strength.

Fig. 6 Relation between hardness and tensile strength of steel. Range up to 300 HB is applicable to the hot-finished steel discussed in this article.

Fatigue Strength. The high-cycle (>1 million) fatigue properties of hot-finished steel, often called the fatigue limit, are more or less directly related to tensile strength and are greatly affected by the surface condition. The fatigue limit of machined specimens is about 40% of the tensile strength, depending on the surface finish. In contrast, unmachined hot-rolled steel, when loaded so that fatigue stresses are concentrated at the surface, will have a considerably lower fatigue limit because of decarburization, surface roughness, and other surface imperfections. For this reason, the location of maximum fatigue stresses should be carefully considered; for structural members designed in hot-finished steel, the surface should be machined off from critically stressed areas or an allowance made for the weakness of the hot-finished surface.

The presence of inclusions in hot-finished steel may also have an adverse effect on the fatigue limit. Large inclusions are considered harmful under the dynamic stresses of impact or fatigue, and the effect is greater in the harder steels.

Low-Temperature Impact Energy. When notch toughness is an important consideration, satisfactory service performance can be ensured by proper selection of the steel that will behave in a tough manner at its lower operating temperature. The Charpy V-notch tests and crack-starter drop-weight tests provide a fairly reliable indication of the tendency toward brittle fracture in service. The transition temperatures of hot-finished steels are controlled principally by their chemical composition and ferrite grain size. For the steels considered in this article, carbon is of primary importance because of its effect is raising the transition temperature, lowering the maximum energy values, and widening the temperature range between completely tough and completely brittle behavior.

Manganese (up to about 1.5%) improves low-temperature properties. Also, as mentioned previously, the transition temperature is affected by the deoxidation practice used. The transition temperature decreases and the energy absorption before fracture at normal temperatures increases in the order of rimmed, capped, semikilled, and killed steels. In addition, killed steels contain larger amounts of silicon or aluminum than semikilled steels, and these elements improve low-temperature toughness and ductility. Because of variations in finishing temperatures and cooling rates, plate thickness influences the grain size and therefore the transition temperature. Extensive data on the impact properties of hot-finished steel are given in the article "Notch Toughness of Steels" in this Volume.

Elevated-Temperature Properties. The steel plate used in pressure vessel applications is often subjected to long-term elevated temperatures. Of the carbon and low-alloy steels used for pressure vessel plate, the behavior of 2.25Cr-1Mo steel (ASTM A 387, Class 22, in Table 9) at elevated temperatures has been studied more thoroughly than any other steel and has become the reference for comparing the elevated-temperature properties of low-alloy steels. Further information on the elevated-temperature properties of 2.25Cr-1Mo steel can be found in the article "Elevated-Temperature Properties of Ferritic Steels" in this Volume.

Directional Properties. An important characteristics of steel plate, known as directionality or fibering, must be considered. During the rolling operations, many inclusions, which are in a plastic condition at rolling temperatures, are elongated in the direction of rolling. At the same time, localized chemical segregates that have formed during solidification of the steel are also elongated. These effects reduce the ductility and impact properties transverse to the rolling direction, but have little or no effect on strength.

Fabrication Considerations

Formability. The cold formability of steel plate is directly related to the yield strength and ductility of the material. The lower the yield strength, the smaller the load required to produce permanent deformation; high ductility allows large deformation without fracture. Therefore, the lower-carbon grades are most easily formed.

Operations such as shearing and blanking are usually limited by the lack of the available facilities as the plate thickness increases. This also applies to bending operations. Of course, an adequate bend radius must be used to avoid fracture. Because of fibering effects, the direction of bend is also important; when the axis of a bend is parallel to the direction of rolling, small bend radii are usually difficult to form because of the danger of cracking.

Machinability. Machining operations are usually performed with little difficulty on most plate steels up to about 0.50% C. Higher-carbon steels can be annealed for softening. Steels with low carbon and manganese content, such as 1015, with large quantities of free ferrite in the microstructure may be too soft and gummy for good machining. Increasing the carbon content (to a steel such as 1025) improves the machinability.

Machining characteristics can be improved by factors that break up the chip as it is removed. This is usually accomplished by the introduction of large numbers of inclusions such as manganese sulfides or complex oxysulfides. These "free-machining" steels are somewhat more expensive, but are cost-effective when extensive machining is involved.

Weldability is a relative term that describes the ease with which sound welds possessing good mechanical properties can be produced in a material. The chief weldability factors are composition, heat input, and rate of cooling. These factors produce various effects, such as grain growth, phase changes, expansion, and contraction, which in turn determine weldability. Heat input and cooling rate are characteristics of the specific process and technique used and the thickness of the metal part being welded. Therefore, weldability ratings should state the conditions under which the rating was determined and the properties and soundness obtained.

For carbon steels, the carbon and manganese contents are the primary elements of the composition factor that determine the effect of the steel of given heating and cooling conditions. The great tonnage of steel used for welded applications consists of low-carbon steel, up to 0.30% C.

Generally, steels with a carbon content less than 0.15% are readily weldable by any method. Steel with a carbon range of 0.15 to 0.30% can usually be welded satisfactorily without preheating, postheating, or special electrodes. For rather thick sections (>25 mm, or 1 in.), however, special precautions such as 40 °C (100 °F) minimum preheat, 40 °C (100 °F) minimum temperature between weld passes, and a 540 to 675 °C (1000 to 1250 °F) stress relief may be necessary.

Higher-carbon and higher-manganese grades can often be welded satisfactorily if preheating, special welding techniques, and postheating and peening are used. In the absence of such precautions to control the rate of cooling and to eliminate high stress gradients, cracks may occur in the weld and base metal. In addition, base metal properties such as strength, ductility, and toughness may be greatly reduced.

All comments about the effect of carbon and manganese on weldability must be qualified in terms of section size because of its relationship to heat input and cooling rate. In welding thicker sections, such as plate, the relatively cold base metal serves to greatly accelerate the cooling rate after welding with the result that plate thickness is a very important

consideration. Figure 7 shows the effect of plate thickness and carbon equivalent on weldability as expressed in terms of a notch bend test.

Fig. 7 Ratio (welded to unwelded) of bend angle for normalized steel plate. A high value of the ratio indicates high weldability. Source: Ref 2

Hot-Rolled Steel Bars and Shapes

Revised by Timothy E. Moss, J.M. Hambright, and T.E. Murphy, Inland Bar and Structural, Division of Inland Steel Company; and J.A. Schmidt, Joseph T. Ryerson and Sons, Inc.

Introduction

HOT-ROLLED STEEL BARS and other hot-rolled steel shapes are produced from ingots, blooms, or billets converted from ingots or from strand cast blooms or billets and comprise a variety of sizes and cross sections. Bars and shapes are most often produced in straight lengths, but bars in some cross sections in smaller sizes are also produced in coils.

The term "bar" includes:

- Rounds, squares, hexagons, and similar cross sections 9.5 mm ($\frac{3}{8}$ in.) and greater across
- Flats greater than 5.16 mm (0.203 in.) in thickness and 152 mm (6 in.) and less in width, or 5.84 mm

- (0.230 in.) and greater in thickness and 203 mm (8 in.) and less in width
- Small angles, channels, tees, and other standard shapes less than 76 mm (3 in.) across
- Concrete-reinforcing bars

The term "shape" includes structural shapes and special shapes. Structural shapes are flanged, are 76 mm (3 in.) or greater in at least one cross-sectional dimension, and are used in structures such as bridges, buildings, ships, and railroad cars. Special shapes are those designed by users for specific applications.

Dimensions and Tolerances

The nominal dimensions of hot-rolled steel bars and shapes are designated in inches or millimeters with applicable tolerances, as shown in ASTM A 6 and A 29. Bars with certain quality descriptors have size limitations; these are covered in discussions of individual product qualities later in this article.

Bars or shapes can be cut to length in the mill by a number of methods, such as hot or cold shearing or sawing. The method used is determined by cross section, grade, and customer requirements. Some end distortion is to be expected from most methods. When greater accuracy in length or freedom from distortion is required, bars or shapes can be cut overlength, then recut on one or both ends by cold sawing or equivalent means.

If a bar or shape requires straightening, prior annealing is sometimes necessary, depending on the grade of steel and the cross-sectional shape of the part. The processing necessary to meet straightness tolerances is not intended to improve either the surface finish or accuracy of cross-sectional shape and may result in increased surface hardness. Length and straightness tolerances for bars and shapes are found in ASTM A 6 and A 29.

Surface Imperfections

Most carbon steel and alloy steel hot-rolled bars and shapes contain surface imperfections with varying degrees of severity. In virtually all cases, these defects are undesirable and may in some applications affect the integrity of the finished product.

Included in the manufacturing process for hot-rolled bars and shapes are various steps designed to minimize or eliminate surface defects. These steps include inspection of both the semifinished and the finished product and either subsequent removal of the defects or rejection of the material if defect removal is not possible. Inspection techniques range from visual inspection of the semifinished material to sophisticated electronic inspection of the finished product. Defects found in the semifinished product can be removed by hot scarfing, grinding, or chipping. Defects in the finished products are generally removed by grinding, turning, or peeling and, to a lesser degree, by chipping.

Currently, it is not technically feasible to produce defect-free hot-rolled bars. With the current demand for high-quality bar products, it is becoming increasingly common to subject hot-rolled bars to a cold-finishing operation, such as turning or grinding, coupled with a sensitive electronic inspection. With this process route, it becomes possible to significantly reduce both the frequency and the severity of surface defects.

Seams, Laps, and Slivers

Seams, laps, and slivers are probably the most common defects in hot-rolled bars and shapes.

Seams are longitudinal defects that can vary greatly in length and depth. It is quite common for steel users to refer to any longitudinal defect as a seam regardless of the true nature of the defect. However, there is a classical definition of a seam, as follows. Gas comes out of the solution as the liquid steel solidifies. This gas is trapped as bubbles or blowholes by the solidifying steel and appears as small holes under the surface of the steel. When the steel is reheated, some areas of the surface may scale off, exposing and oxidizing the interior of these blowholes. This oxidation prevents the blowholes from welding shut during rolling. This rolling then elongates the steel, resulting in a longitudinal surface discontinuity--a seam. As viewed in the cross section, seams are generally characterized as being perpendicular to the surface, completely surrounded by decarburization, and associated with disperse oxides.

Laps are mechanical defects that occur during the hot rolling of both semifinished and finished material. Laps are nothing more than a folding over of the material, resulting, for example, from gouging during the rolling process or misalignment of the pass lines or rolls. As viewed in the cross section, laps are characterized as being at an angle from the steel surface; they have decarburization on one side only of the defect and often contain entrapped scale.

Slivers usually appears as a scablike defect, adhering on one end to the surface of the hot-rolled steel. They are normally pressed into the surface during hot rolling. They can originate from short, rolled out defects such as torn corners that are not removed during conditioning. They can also result from conditioning gouges or mechanical gouges during rolling. Although there is no specific metallographic definition of slivers, metallographic examination can be used to determine the origin of these defects.

Decarburization

Another condition that could be considered a surface defect is decarburization. This condition is present to some degree on all hot-rolled steel. Decarburization occurs at very high temperatures when the surface carbon of the steel reacts with the oxygen in the furnace atmosphere. This loss of surface carbon results in a surface that is softer and unsuitable for any application involving wear or fatigue. Because of the existence of this condition, steel ordered for critical applications can be produced oversize and then ground to desired size.

Allowance for Surface Imperfections in Machining Applications

Experience has shown that when purchasers order hot-rolled or heat-treated bars that are to be machined, it is advisable for the purchaser to make adequate allowances for the removal of surface imperfections and to specify the sizes accordingly. These allowances depend on the way the surface metal is removed, the length and size of the bars, the straightness, the size tolerance, and the out-of-round tolerance. Bars are generally straightened before machining. For special quality carbon steel bars and regular quality alloy steel bars, either resulfurized or nonresulfurized (see the article "Cold-Finished Steel Bars" in this Volume), it is advisable that allowances for centerless-turned or centerless-ground bars be adequate to permit stock removal of not less than the amount shown below:

Bar diameter		Recommended minimum machining allowance per side, % of specific size	
mm	in.	Nonresulfurized	Resulfurized
≤ 51	≤ 2	2.6	3.4
>51	>2	1.6	2.4

Source: Ref 1

Note that these allowances are based on bars within straightness tolerance. Also, because straightness is a function of length, additional machining allowance may be required for turning long bars on centers. For steel bars subject to magnetic particle inspection, additional stock removal is recommended, as indicated in Table 1.

Table 1 Recommended minimum stock removal for steel bars subject to magnetic particle inspection

Hot-rolled size	Minimum stock removal from the surface ^(a)
-----------------	---

mm	in.	mm	in.
Up to 12.7	Up to $\frac{1}{2}$	0.76	0.030
>12.7-19	$>\frac{1}{2}-\frac{3}{4}$	1.14	0.045
>19-25	$>\frac{3}{4}-1$	1.52	0.060
>25-38	$>1-1\frac{1}{2}$	1.90	0.075
>38-51	$>1\frac{1}{2}-2$	2.29	0.090
>51-64	$>2-2\frac{1}{2}$	3.18	0.125
>64-89	$>2\frac{1}{2}-3\frac{1}{2}$	3.96	0.156
>89-114	$>3\frac{1}{2}-4\frac{1}{2}$	4.75	0.187
>114-152	$>4\frac{1}{2}-6$	6.35	0.250
>152-191	$>6-7\frac{1}{2}$	7.92	0.312
>191-229	$>7\frac{1}{2}-9$	9.52	0.375
>229-254	>9-10	11.10	0.437

(a) The minimum reduction in diameter of rounds is twice the minimum stock removal from the surface.

The allowances described above are usually more than sufficient to remove surface imperfections and result in considerable loss of material. Therefore, most experienced fabricators remove considerably less stock than recommended

and take their chances on occasional difficulties. In conventional practice, depth of machining for hot-rolled bars is 1.6 mm ($\frac{1}{16}$ in.) for bars 38 to 76 mm ($1\frac{1}{2}$ to 3 in.) in diameter, and 3.2 mm ($\frac{1}{8}$ in.) for bars over 76 mm (3 in.) in diameter.

Surface Treatment

It is uncommon for hot-rolled steel bars and shapes to be descaled by the producer or protected from the weather during transit. Most cleaning and coating operations are done either by the customer or by an intermediate processor.

Descaling of hot-rolled bars and shapes is generally done by either pickling or blasting, depending on the end use. There are several subsequent coatings that can be used. Oil is both the simplest and the least expensive to use and acts as a temporary rust preventive. Lime, in addition to serving as a rust preventive, can serve as a carrier for lubricants used during cold drawing or cold forging. A more sophisticated system includes descaling, followed by a zinc phosphate coating, coupled with a dry lubricant. This system provides some rust protection and serves as a lubricant for cold-forming operations.

Heat Treatment

Hot-rolled low-carbon and medium-carbon steel bars and shapes are often used in the as-rolled condition, but hot-rolled bars of higher-carbon steel and most hot-rolled alloy steel bars must be heat treated in order to attain the hardness and microstructure best suited for the final product or to make them suitable for processing. Such heat treatment consists of one or more of the following: some form of annealing, stress relieving, normalizing, quenching, and tempering.

Ordinary annealing is the term generally applied to heat treatment used to soften steel. The steel is heated to a suitable temperature, held there for some period of time, and then cooled; specific times, temperatures, and cooling rates vary. Maximum hardness compatible with common practice can be specified.

Annealing for specified microstructures can be performed to obtain improved machinability or cold-forming characteristics. The structures produced may consist of lamellar pearlite or spheroidized carbides. Special control of the time and temperature cycles is necessary. A compatible maximum hardness can be specified.

Stress relieving involves heating to a sub-critical temperature and then cooling. For hot-rolled bars, the principal reason for stress relieving is to minimize distortion in subsequent machining. It is used to relieve the stresses resulting from cold-working operations, such as special machine straightening.

Normalizing involves heating to a temperature above the critical temperature range and then cooling in air. A compatible maximum hardness can be specified.

Hardening by quenching consists of heating steel to the correct austenitizing temperature, holding at that temperature for a sufficient time to produce homogeneous austenite, and quenching in a suitable medium (water, oil, synthetic oil or polymer, molten salts, or low-melting metals) depending on chemical composition and section thickness.

Tempering is an operation performed on normalized or quenched steel bars. In this technique, the bars are reheated to a predetermined temperature below the critical range and then cooled under suitable conditions.

When a hardness requirement is specified for normalized and tempered bars, the bars are ordinarily produced to a range of hardnesses equivalent to a 0.4 mm range of Brinell impression diameters. Quenched and tempered bars are ordinarily produced to a 0.3 mm range of Brinell impression diameters. Quenched and tempered bars can also be produced to minimum mechanical property requirements.

Product Requirements

Hot-rolled steel bars and shapes can be produced to chemical composition ranges or limits, mechanical property requirements, or both. The mechanical testing of hot-rolled steel bars and shapes can include tensile, Brinell or Rockwell hardness, bend, Charpy impact, fracture toughness, and short-time elevated-temperature tests, as well as test for elastic limit, proportional limit, and offset yield strength, which require the use of an extensometer or plotting of a stress-strain curve. These tests are covered by ASTM A 370 and other ASTM standards.

Other tests sometimes required include the measurement of grain size and hardenability. Austenitic grain size is determined by the McQuaid-Ehn test, which is described in ASTM E 112. This test involves metallographic examination of a carburized specimen to observe prior austenitic grain boundaries. Hardenability can be measured by several methods, the most common being the Jominy end-quench test, as described in ASTM A 255 (see the article "Hardenability of Carbon and Low-Alloy Steels" in this Volume).

Soundness and homogeneity can be evaluated by fracturing. The fracture test is commonly applied only to high-carbon bearing quality steel. Location of samples, number of tests, details of testing technique, and acceptance limits based on the test should be established in each instance.

Testing for nonmetallic inclusions consists of careful microscopic examination (at 100×) of prepared and polished specimens. The specimens should be taken on a longitudinal plane midway between the center and surface of the product. Location of specimens, number of tests, and interpretation of results should be established in each instance. Typical testing procedures are described in ASTM E 45. Nonmetallic inclusion content can also be measured on the macroscopic scale by magnetic particle tests such as those described in AMS 2300 and 2301. These tests involve the measurement of inclusion frequency and severity in a sampling scheme that represents the interior of the material.

Surface and subsurface nonuniformities are revealed by magnetic particle testing. This test was developed for, and is used on, fully machined or ground surfaces of finished parts. When the magnetic particle test is to be applied to bar stock, short-length samples should be heat treated and completely machined or ground.

Tensile and hardness tests are the most common mechanical tests performed on hot-rolled steel bars and shapes. Hardness is a relatively simple property to measure, and it is closely related to tensile strength, as shown in Fig. 1. When Fig. 2 is used together with Fig. 1, a simple hardness test can give an estimate of yield strength and elongation, as well as tensile strength.

Fig. 1 Relationship between hardness and tensile strength of steel. Range up to 300 HB is applicable to the hot-finished steel discussed in this article. Source: Ref. 2

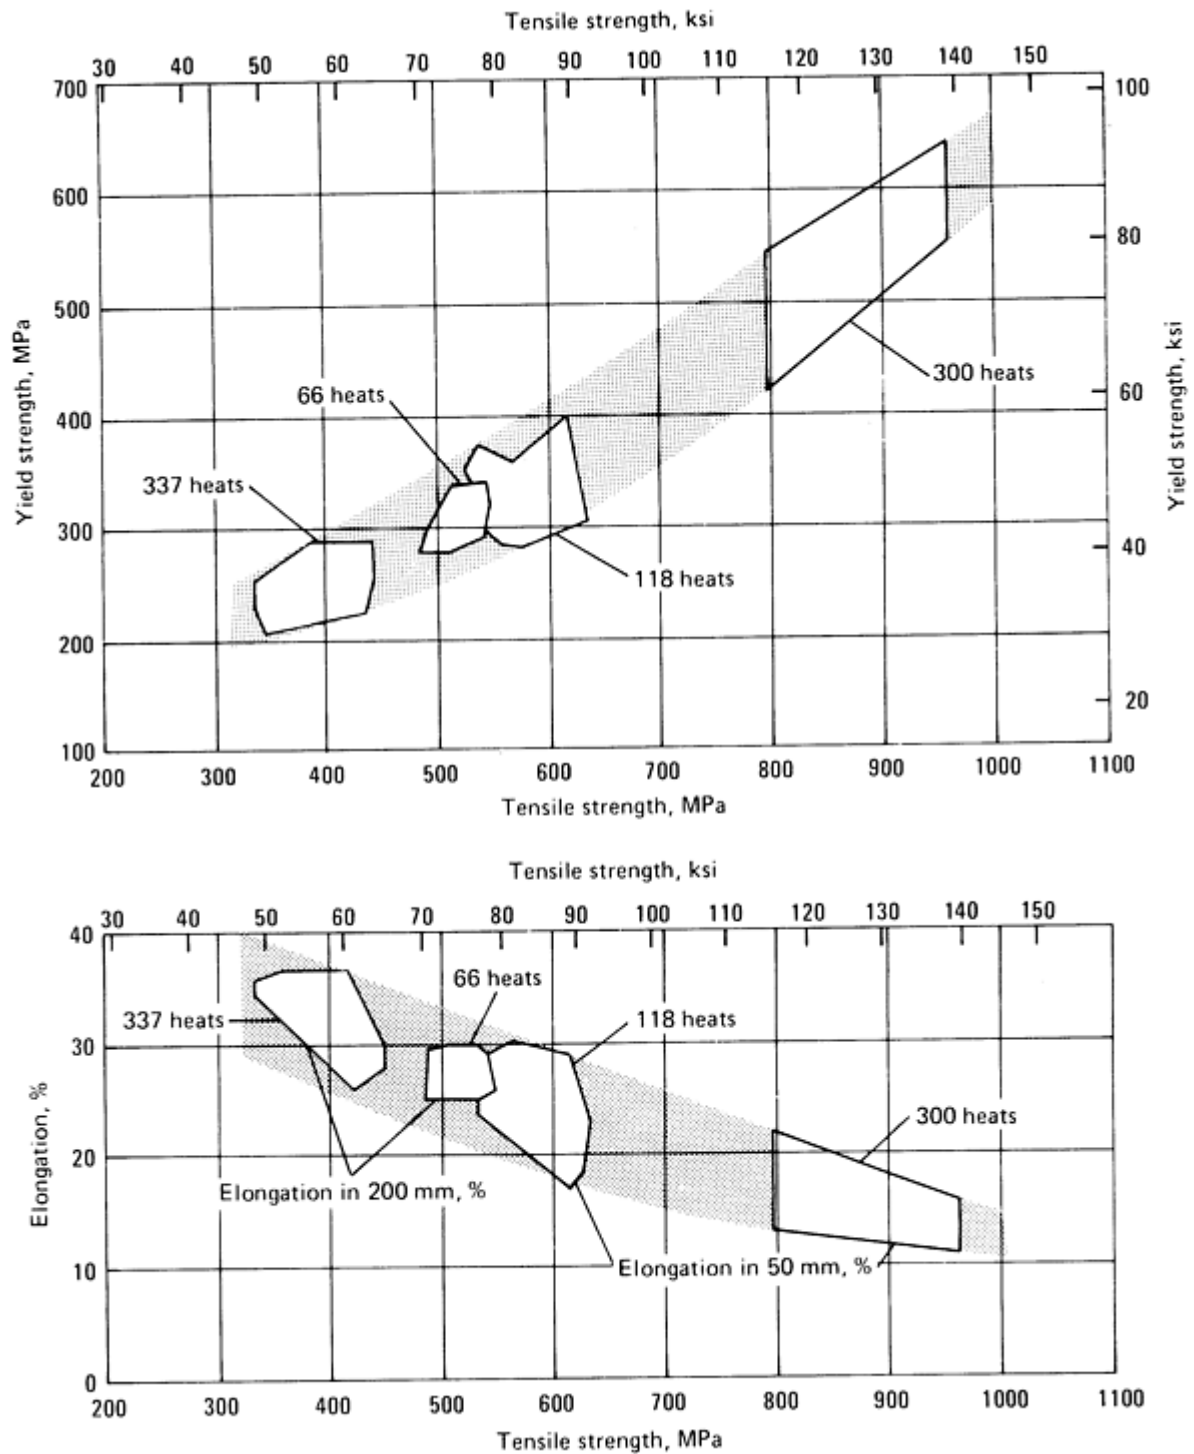

Fig. 2 Relation of tensile properties for hot-rolled carbon steel

It is not practicable to set definite limitations on tensile strength or hardness for carbon or alloy steel bars in the as-rolled condition. For mill-annealed steel bars, there is a maximum tensile strength or a maximum hardness (Table 2) that can be expected for each grade of steel. For steel bars in the normalized condition, maximum hardness, maximum tensile strength, minimum hardness, or minimum tensile strength can be specified. For normalized and tempered bars and for quenched and tempered bars, either maximum and minimum hardness or maximum and minimum tensile strength can be specified; for either property, the range that can be specified varies with tensile strength and is equivalent to a 0.4 mm range of Brinell indentation diameters at any specified location for normalized and tempered bars and to a 0.3 mm range for quenched and tempered bars.

Table 2 Lowest maximum hardness that can be expected for hot-rolled steel bars, billets, and slabs with ordinary mill annealing

(a) Specific microstructure requirements may necessitate modification of these hardness numbers.

It is essential that the purchaser specify the positions at which hardness readings are to be taken. When both hardness and tensile strength are specified at the same position, the limits should be consistent with each other. When hardness limits are specified as surface values, they may be inconsistent with tensile-test values, which of necessity are properties of the bulk metal; the inconsistency will vary according to the size of the bar and the hardenability of the steel. The purchaser should specify limits that take this inconsistency into account.

If the locations of hardness readings are not specified on the purchaser's order or specification, the hardness values are applicable to the bar surface after removal of decarburization. Hardness correction factors for bars of various diameters as described in ASTM E 18 should be employed if a flat area is not available on the bar tested.

Generally, yield strength, elongation, and reduction in area are specified as minimums for steel only in the quenched and tempered or the normalized and tempered condition, and they should be consistent with ultimate tensile strength or hardness. When quenched and tempered bars are cold worked by cold straightening, stress relieving may be required to restore elastic properties and to improve ductility.

Product Categories

Hot-rolled carbon steel bars are produced to two primary quality levels: merchant quality and special quality. Merchant quality is the lower quality level and is not suitable for any operation in which internal soundness or freedom from surface imperfections is of primary importance. Special, quality includes all bar categories with end-use-related and restrictive quality requirements.

The mechanical properties of hot-rolled carbon steel bars in the as-rolled condition are influenced by:

- Chemical composition
- Thickness or cross-sectional area
- Variables in mill design and mill practice

Carbon content is the dominant factor. The minimum expected mechanical properties of commonly used grades of hot-rolled carbon steel bars are shown in Fig. 3.

Fig. 3 Estimated minimum tensile properties of selected hot-rolled carbon steel bars

Quality descriptors for hot-rolled alloy steel bars are related to suitability for specific applications. Characteristics considered include inclusion content, uniformity of chemical composition, and freedom from surface imperfections.

Carbon steel and alloy steel structural shapes and special shapes do not have specific quality descriptors but are covered by several ASTM specifications (Table 3). In most cases, these same specifications also cover structural quality steel bars. The ASTM specifications covering other qualities of hot-rolled bars are listed in Table 4. The various categories of hot-rolled steel bar products and their characteristics are described in the following sections.

Table 3 Typical ASTM specifications for structural quality steel bars and steel structural shapes

Covered in ASTM A 6

Specification	Steel type and condition
Carbon steels	
A 36 ^{(a)(b)}	Carbon steel plates, bars, and shapes
A 131 ^(c)	Carbon and HSLA steel plates, bars, shapes, and rivets for ships
A 529	Carbon steel plates, bars, shapes, and sheet piling with minimum yield strength of 290 MPa (42 ksi)
A 709	Carbon, alloy, and HSLA steel plates, bars, and shapes for bridges
Alloy steel	
A 710	Age-hardening low-carbon Ni-Cu-Cr-Mo-Nb and Ni-Cu-Nb alloy steel plates, bars, and shapes
High-strength low-alloy (HSLA) steels	
A 131 ^(c)	See above under Carbon Steel
A 242	HSLA steel plates, bars, and shapes
A 572	Nb-V HSLA steel plates, bars, shapes, and sheet piling
A 588	HSLA steel plates, bars, and shapes with minimum yield point of 345 MPa (50 Ksi)
A 633	Normalized HSLA steel plates, bars, and shapes
A 690	HSLA steel H-piles and sheet piling for use in marine environments

(a) This ASTM specification is also published by the American Society of Mechanical Engineers, which adds an S in front of the A.

(b) See also Canadian Standards Association (CSA) specification G40.8.

(c) See also Section 39 of the ABS specifications.

Table 4 Typical ASTM specifications for hot-rolled steel bars

See Table 3 for ASTM specifications for structural quality bars and structural shapes.

Specification	Steel type and condition
Carbon steels	
A 321 ^(a)	Quenched and tempered carbon steel bars
A 575 ^(a)	Merchant quality carbon steel bars
A 576 ^(a)	Special quality carbon steel bars
A 663 ^(a)	Merchant quality carbon steel bars subject to mechanical property requirements
A 675 ^(a)	Special quality carbon steel bars subject to mechanical property requirements
Alloy steels	
A 295	Bearing quality high-carbon chromium steel billets, forgings, tube rounds, bars, rods, and tubes
A 304 ^(a)	Alloy steel bars subject to end-quench hardenability requirements
A 322 ^(a)	Alloy steel bars for regular constructional applications
A 434 ^(a)	Quenched and tempered alloy steel bars, hot rolled or cold finished
A 485	Bearing quality high-carbon chromium steel billets, tube rounds, bars, and tubes modified for high hardenability
A 534	Carburizing alloy steel billets, tube rounds, bars, rods, wire, and tubes of bearing quality
A 535	Special quality alloy steel billets, bars, tube rounds, rods, and tubes for the manufacture of antifriction bearings

(a) Covered in ASTM A 29

Merchant Quality Bars

Merchant quality is the least restrictive descriptor for hot-rolled carbon steel bars. Merchant quality bars are used in the production of noncritical parts of bridges, buildings, ships, agricultural implements, road-building equipment, railway equipment, and general machinery. These applications require only mild cold bending, mild hot forming, punching, and welding. Mild cold bending is bending in which a generous bend radius is used and in which the axis of the bend is at right angles to the direction of rolling.

Merchant quality bars should be free from visible pipe; however, they may contain pronounced chemical segregation, and for this reason, product analysis tolerances are not appropriate. Internal porosity, surface seams, and other surface irregularities may be present and are generally expected in bars of this quality. Consequently, merchant quality bars are not suitable for applications that involve forging, heat treating, or other operations in which internal soundness or freedom from surface imperfections is of primary importance.

Grades. Merchant quality bars can be produced to meet both chemical composition (heat analysis only) and mechanical properties. These steels can be supplied to chemical compositions within the ranges of 0.50% C (max), 0.60% Mn (max), 0.04% P (max), and 0.05% S (max), but are not produced to meet any specific silicon content, grain size, or any other requirement that would dictate the type of steel produced.

Merchant quality steel bars do not require the chemical ranges typical of standard steels. They are produced to wider carbon and manganese ranges and are designated by the prefix "M."

When ordering merchant quality bars to meet mechanical properties, the following strength ranges are to be used up to a maximum of 655 MPa (95 ksi):

- 70 MPa (10 ksi) for minimums up to but not including 415 MPa (60 ksi)
- 80 MPa (12 ksi) for minimums from 415 MPa (60 ksi) up to but not including 460 MPa (67 ksi)
- 100 MPa (15 ksi) for minimums from 460 to 550 MPa (67 to 80 ksi)

Specification ASTM A 663 defines the requirements for hot-wrought merchant quality carbon steel bars and bar-size shapes intended for noncritical constructional applications.

Sizes. Merchant quality steel rounds are not produced in diameters greater than 76 mm (3 in.).

Special Quality Bars

Special quality bars are employed when end use, method of fabrication, or subsequent processing treatment requires characteristics not available in merchant quality bars. Typical applications, including many structural uses, require hot forging, heat treating, cold drawing, cold forming, and machining.

Special quality bars are required to be free from visible pipe and excessive chemical segregation. Also, they are rolled from billets that have been inspected and conditioned, as necessary, to minimize surface imperfections. Frequency and degree of surface imperfections are influenced by chemical composition, type of steel, and bar size. Resulturized grades, certain low-carbon killed steels, and boron-treated steels are most susceptible to surface imperfections.

Some end uses or fabricating procedures can necessitate one or more extra requirements. These requirements include special hardenability, internal soundness, nonmetallic inclusion rating, and surface condition and are described in the AISI manual covering hot-rolled bars. The quality descriptor for bars to which only one of these special requirements is applied is Restrictive Requirement Quality A. When a single special restriction other than the four mentioned above is applied, the quality descriptor is Restrictive Requirement Quality B. Multiple Restrictive Requirement Quality bars are those to which two or more restrictive requirements are applied.

Special quality steel bars can be produced using rimmed, capped, semikilled, or killed deoxidation practice. The appropriate type is dependent on chemical composition, quality, and customer specifications. Killed steels can be produced to coarse or fine austenitic grain size.

Special quality steel bars are produced to product chemical composition tolerances and can be purchased on the basis of heat composition. Special quality steel bars can also be produced to meet mechanical property requirements. The tensile

strength ranges are identical to those presented in the section "Merchant Quality Bars" in this article. Additional information on mechanical property requirements and test frequencies is available in the appropriate ASTM specifications.

Sizes. Special quality steel bars are commonly produced in the following sizes:

- *Rounds:* 6.4 to 254 mm ($\frac{1}{4}$ to 10 in.)
- *Squares:* 6.4 to 154 mm ($\frac{1}{4}$ to $6\frac{1}{16}$ in.)
- *Round-cornered squares:* 9.5 to 203 mm ($\frac{3}{8}$ to 8 in.)
- *Hexagons:* 9.5 to 103 mm ($\frac{3}{8}$ to $4\frac{1}{16}$ in.)
- *Flats:* greater than 5.16 mm (0.203 in.) in thickness and 152 mm (6 in.) and less in width, or 5.84 mm (0.230 in.) and greater in thickness and 203 mm (8 in.) and less in width

Common size ranges have not been established for special quality bars of other shapes, including bar-size shapes, ovals, half-ovals, half-rounds, octagons, and special bar-size shapes.

Carbon Steel Bars for Specific Applications

Cold-working quality is the descriptor (replacing the older terminology of scrapless nut, cold forging, cold heading, and cold extrusion qualities) for hot-rolled bars used in the production of solid or hollow shapes by means of severe cold plastic deformation, such as (but not limited to) upsetting, heading, forging, and forward or backward extrusion involving movement of metal by expansion and/or compression. Such processing normally involves special inspection standards and requires sound steel of special surface quality and uniform chemical composition. If steel of the type or chemical composition specified does not have adequate cold-forming characteristics in the as-rolled condition, a suitable heat treatment, such as annealing or spheroidize annealing, may be necessary.

Axle Shaft Quality. Bars of axle shaft quality are produced for the manufacture of power-driven axle shafts for cars, trucks, and other vehicles. Because of their design or method of manufacture, these axles either are not machined all over or undergo less than the recommended amount of stock removal for proper cleanup of normal surface imperfections. Therefore, it is necessary to minimize the presence of injurious surface imperfections in bars of axle shaft quality through the use of special rolling practices, special billet and bar conditioning, and selective inspection.

Cold-Shearing Quality. There are limits to the sizes of hot-rolled steel bars that can normally be cold sheared without specially controlled production procedures. When the cold shearing of larger bars is desirable, it is recommended that cold-shearing quality bars be ordered. Bars of this quality have characteristics that prevent cracking even in these larger sizes. Cold-shearing quality bars are not produced to specific requirements such as hardness, microstructure, shear life, or productivity. Maximum size (cross-sectional area) limitations for the cold shearing of hot-rolled steel bars without the specially controlled production procedures, and of cold-shearing quality bars, are given in the AISI manual that covers hot-rolled bars. If even larger bars are to be cold sheared, cold-shearing behavior can be further improved by suitable prior heat treatment.

Structural quality is the descriptor for hot-rolled bars used in the construction of bridges and buildings by riveting, bolting, or welding and for general structural purposes. The general requirements for bars of this quality are given in ASTM A 6; individual ASTM specifications are listed in Table 3.

Additional qualities of carbon steel bars are available for specific requirements. Such qualities are related to application and processing. They include:

- File quality
- Gun barrel quality
- Gun receiver quality

- Shell steel quality A
- Shell steel quality B
- Shell steel quality C
- Shell steel quality D

Alloy Steel Bars

Hot-rolled alloy steel bars are commonly produced in the same size as special quality steel bars. Common size ranges have not been established for other shapes of hot-rolled alloy steel bar, including bar-size shapes, ovals, half-ovals, half-rounds, octagons, and special bar-size shapes.

Hot-rolled alloy steel bars are covered by several ASTM specifications (Tables 3 and 4). Many of the alloys covered in these specifications are standard AISI-SAE grades (Table 5).

Table 5 AISI-SAE grades of hot-rolled alloy steel bars in ASTM specifications

ASTM specification	AISI-SAE grades
A 295	52100, 51100, 50100
A 304	All H grades except 4626H and 86B30H
A 322	All standard grades except 4032, 4042, 4135, 4422, 4427, 4617, 50B40, 5046, 5060, 5115, 5117, 50100, 8115, 86B45, 8650, 8660, 9310, and 94B15
A 434	By agreement
A 534	4023, 4118, 4320, 4620, 4720, 5120, 8620, E-3310, E-9310
A 535	3310, 4320, 4620, 4720, 4820, 52100, 52100 Mod. 1, 52100 Mod. 2, 52100 Mod. 3, 52100 Mod. 4, 8620, 9310

Hot-rolled alloy steel bars are also covered by several quality descriptors, which are discussed below. As with all quality descriptors, these descriptors differentiate bars on the basis of characteristic properties required to meet the particular conditions encountered during fabrication or use.

Regular quality is the basic or standard quality for hot-rolled alloy steel bars, such as those covered by ASTM A 322. Steel for this quality are killed, are usually produced to fine grain size, and are melted to chemical composition limits. Bars of this quality are inspected, conditioned, and tested to meet the normal requirements for regular construction applications for which alloy steel is used.

Axle Shaft Quality. Alloy steel bars of axle shaft quality are similar to carbon steel bars of the same quality (see the discussion of axle shaft quality bars in the section "Carbon Steel Bars for Specific Applications" in this article).

Ball and roller bearing quality and bearing quality apply to alloy steel bars intended for antifriction bearings. These bars are usually made from steels of the AISI-SAE standard alloy carburizing grades and the AISI-SAE high-carbon chromium series. These steels can be produced in accordance with ASTM A 534, A 535, A 295, or A 485 (Table 4). Bearing quality steel bars require restricted melting and special teeming, heating, rolling, cooling, and conditioning practices to meet rigid quality standards. Steelmaking practices may include vacuum treatment. The foregoing requirements include thorough examination for internal imperfections by one or more of the following methods: macroetch testing, microscopic examination for nonmetallic inclusions, ultrasonic inspection, and fracture testing.

It is not practical to furnish bearing quality steel bars in sizes exceeding 64,500 mm² (100 in.²) in cross-sectional area to the same rigid requirements as those for bars in smaller sizes because of insufficient hot working in the larger bars. Usually, bars over 102 mm (4 in.) in thickness are forged to 102 mm (4 in.) square or smaller for testing.

Cold-Shearing Quality. Alloy steel bars of cold-shearing quality are similar to carbon steel bars of the same quality (see the discussion of cold-shearing quality bars in the section "Carbon Steel Bars for Specific Applications" in this article).

Cold-working quality, which replaces the older terminologies cold-heading quality and special cold-heading quality, is the descriptor for hot-rolled bars used in the production of solid or hollow shapes by means of severe cold plastic deformation, such as (but not limited to) upsetting, heading, forging, and forward or backward extrusion involving movement of metal by expansion and/or compression. Such processing normally involves special inspection standards and requires sound steel of special surface quality and uniform chemical composition. If steel of the type or chemical composition specified does not have adequate cold-forming characteristics in the as-rolled condition, a suitable heat treatment, such as annealing or spheroidize annealing, may be necessary.

Aircraft quality and magnaflux quality are the descriptors used for alloy steel bars for critical or highly stressed parts of aircraft and for other similar or corresponding purposes involving additional stringent requirements such as magnetic particle inspection, additional discard, macroetch tests, and hardenability control. To meet these requirements, exacting steelmaking, rolling, and testing practices must be employed. These practices are designed to minimize detrimental inclusions and porosity. Phosphorus and sulfur are usually limited to 0.025% maximum each.

Many parts for aircraft, missiles, and rockets require aircraft quality alloy steel bars. Magnetic particle testing as in AMS 2301 is sometimes specified for such applications. Some very critical aircraft, missile, and rocket applications require alloy steel bars of a quality attained only by vacuum melting or by an equivalent process. The requirements of AMS 2300 are sometimes specified for such applications.

Aircraft quality alloy steel bars are ordinarily made to Aerospace Material Specifications published by the Society of Automotive Engineers. Typical examples of parts for aircraft engines and airframes made from bars covered by AMS specifications are given in Table 6.

Table 6 Specifications and grades of alloy steel bars for aircraft parts

Part	AMS specification	AISI-SAE grade or approximate grade
Aileron, rudder, and, and elevator hinge pins	6415	E4340

Structural quality is the descriptor for hot-rolled bars used in the construction of bridges and buildings by riveting, bolting, or welding and for general structural purposes. The general requirements for bars of this quality are given in ASTM A 6; the only individual ASTM specification referred to in A 6 that pertains to alloy steel bars is A 710.

Additional Qualities. The quality designations shown below apply to alloy steel bars intended for rifles, guns, shell, shot, and similar applications. They may involve requirements for amount of discard, macroetch testing, surface quality, or magnetic particle testing, as indicated in the product specification:

- AP shot quality
- AP shot magnaflux quality
- Gun quality
- Rifle barrel quality
- Shell quality
- Shell magnaflux quality

High-Strength Low-Alloy Steel Bars

In addition to the carbon steel and alloy steel bars of structural quality discussed in preceding sections of this article, ASTM A 6 also lists several specifications covering high-strength low-alloy (HSLA) steel bars of structural quality (Table 3). High-strength low-alloy steel bars are also covered in SAE J 1442.

Bars of these steels offer higher strength than that of carbon steel bars and are frequently selected for applications in which weight saving is important. They also offer increased durability, and many offer increased resistance to atmospheric corrosion. Additional information on HSLA steels is available in the articles "High-Strength Structural and High-Strength Low-Alloy Steels," "High-Strength Low-Alloy Steel Forgings" and "Bulk Formability of Steels" in this Volume.

Microalloyed steel bars constitute a class of special quality carbon steels to which small amounts of alloying elements such as vanadium, niobium, or titanium have been added. Microalloyed steels in the as-hot-rolled condition are capable of developing strengths higher than those of the base carbon grades through precipitation hardening. In some cases, strength properties comparable to those of the quenched and tempered base grade can be attained. These steels are finding increased application in shafting and automotive forgings.

Concrete-Reinforcing Bars

Concrete-reinforcing bars are available as either plain rounds or deformed rounds. Deformed reinforcing bars are used almost exclusively in the construction industry to furnish tensile strength to concrete structures. The surface of the deformed bar is provided with lugs, or protrusions, which inhibit longitudinal movement relative to the surrounding concrete. The lugs are hot formed in the final roll pass by passing the bars between rolls into which patterns have been cut. Plain reinforcing bars are used more often for dowels, spirals, structural ties, and supports than as substitutes for deformed bars. Concrete-reinforcing bars are supplied either straight and cut to proper length, or bent or curved in accordance with plans and specifications.

Grades. Deformed and plain concrete-reinforcing bars rolled from billet steel are produced to the requirements of ASTM A 615 or A 706. For special applications that require deformed bars with a combination of strength, weldability, ductility, and improved bending properties, ASTM A 706 is specified, which is an HSLA steel. Deformed and plain concrete-reinforcing bars are also available rolled from railroad rails (ASTM A 616) and from axles for railroad cars (ASTM A 617), Specification ASTM A 722 covers deformed and plain uncoated high-strength steel bars for prestressing concrete structures.

Sizes. Numbers indicating sizes of reinforcing bars correspond to nominal bar diameter in eighths of an inch for sizes 3 through 8; this relationship is approximate for sizes 9, 10, 11, 14, and 18. The nominal values for bar diameter, cross-sectional area, and weight per unit length corresponding to these size numbers are given in Table 7. The nominal cross-sectional area and the nominal diameter of a deformed bar are the same as those of a plain bar of equal weight per foot.

Table 7 Dimensions of deformed and plain concrete-reinforcing bars of standard sizes

Bar size	Nominal diameter		Cross-sectional area		Nominal weight	
	mm	in.	mm ²	in. ²	kg/m	lb/ft
3	9.52	0.375	71	0.11	0.560	0.376
4	12.70	0.500	129	0.20	0.994	0.668
5	15.88	0.625	200	0.31	1.552	1.043
6	19.05	0.750	284	0.44	2.235	1.502

7	22.22	0.875	387	0.60	3.042	2.044
8	25.40	1.000	510	0.79	3.973	2.670
9	28.65	1.128	645	1.00	5.059	3.400
10	32.26	1.270	819	1.27	6.403	4.303
11	35.81	1.410	1006	1.56	7.906	5.313
14	43.00	1.693	1452	2.25	11.384	7.65
18	57.33	2.257	2581	4.00	20.238	13.60

Structural Shapes

Structural shapes, as stated previously, are flanged shapes 76 mm (3 in.) and greater in at least one cross-sectional dimension (smaller shapes are referred to as bar-size shapes) and are used in the construction of structures such as bridges, buildings, ships, and railroad cars. Included in this product category are regular structural shapes (see ASTM A 6), such as standard beams, wide-flange beams, columns, light beams, joists, stanchions and bearing piles, and certain tees, along with special structural shapes, which are those designed for specialized applications and that have dimensions and/or values of weight per foot that do not conform to regular shapes. Bar-size structural shapes (angles, channels, tees, and zees with greatest cross-sectional dimension less than 76 mm, or 3 in.) are considered to be in the merchant quality bar category rather than the structural shape category.

The common method of designating sizes of structural shapes is as follows:

- *Beams and channels*: By depth of cross section and weight per foot.
- *Angles*: By length of legs and thickness in fractions of an inch or, more commonly, by length of legs and weight per foot. The longer leg of an unequal angle is commonly stated first
- *Tees*: By width of flange, overall depth of stem, and weight per foot, in that order
- *Zees*: By depth, width of flanges, and thickness in fractions of an inch or by depth, flange width, and weight per foot
- *Wide-flange shapes*: By depth, width across flange, and weight per foot, in that order

Most structural shapes are produced to meet specific standard specifications, such as those listed in Table 3. Structural shapes are generally furnished to chemical composition limits and mechanical property requirements.

Special requirements are sometimes specified for structural shapes to adapt them to conditions they will encounter during fabrication or service. These requirements may include specific deoxidation practices, additional mechanical tests, or nondestructive testing.

Special Shapes

Special shapes are hot-rolled steel shapes made with cross-sectional configurations uniquely suited to specific applications. Examples of custom-designed shapes are track shoes for tractors or tanks and sign-post standards.

The only type of standard shape in high production that falls in this classification is rail. Railroad rails of the standard American tee rail shape are produced from carbon steel to the dimensional, chemical, and other requirements of the American Railway Engineering Association (AREA). The sizes of railroad rails are designated in pounds per yard of

length; rails are furnished in 40 to 64 kg (90 to 140 lb) sizes. The most common sizes are 52, 60, 62, and 64 kg (115, 132, 136, and 140 lb). The ordinary length of railroad rails is 12 m (39ft). Carbon steel tee rails for railway track are covered by ASTM A 1; rail-joint bars and tie plates are covered in ASTM A 3, A 4, A 5, A 49, A 67, and A 241.

Light rails are available for light duty, such as in mines and amusement park rides, in sizes from 6.8 to 39 kg (15 to 85 lb). Light rails are covered by specifications of the American Society of Civil Engineers (ASCE).

Crane rails generally have heavier heads and webs than those of railroad rails in order to withstand the heavy loads imposed on them in service. Crane rails in sizes from 18 to 79 kg (40 to 175 lb) are furnished to ASCE, ASTM, and producers' specifications.

Cold-Finished Steel Bars

Revised by the ASM Committee on Cold-Finished Bars*

Introduction

COLD-FINISHED STEEL BARS are carbon and alloy steel bar products (round, square, hexagonal, flat, or special shapes) that are produced by cold finishing previous hot-wrought bars by means of cold drawing, cold forming, turning, grinding, or polishing (singly or in combination) to yield straight lengths or coils that are uniform throughout their length. Not covered in this article are flat-rolled products such as sheet, strip, or plate, which are normally cold finished by cold rolling, or cold-drawn tubular products.

Cold-finished bars fall into five classifications:

- Cold-drawn bars
- Turned and polished (after cold drawn or hot roll) bars
- Cold-drawn, ground, and polished (after cold draw) bars
- Turned, ground, and polished bars
- Cold-drawn, turned, ground, and polished bars

Cold-drawn bars represent the largest tonnage production and are widely used in the mass production of machined and other parts. They have attractive combinations of mechanical and dimensional properties.

Turned and polished bars have the mechanical properties of hot-rolled products but have greatly improved surface finish and dimensional accuracy. These bars are available in sizes larger than those that can be cold drawn. Turned bars are defect and decarb free.

Cold-drawn, ground, and polished bars have the increased machinability, tensile strength, and yield strength of cold-drawn bars together with very close size tolerances. However, cold-drawn, ground, and polished bars are not guaranteed to be defect free.

Turned, ground, and polished bars have superior surface finish, dimensional accuracy, and straightness. These bars find application in precision shafting and in plating, where such factors are of primary importance.

Cold-drawn, turned, ground, and polished bars have improved mechanical properties, close size tolerances, and a surface free of imperfections.

Bar Sizes

Cold-finished steel bars are available in a wide variety of sizes and cross-sectional shapes. Normally, they are furnished in straight lengths, but in some sizes and cross sections they may be furnished in coils. Cold-finished steel bars are available with nominal dimensions designated in either inches or millimeters. Cold-finished product is available in standard size increments, which vary by size range. Special sizes can be negotiated depending on hot mill increments and cold-finish tooling. The sizes in which they are commonly available in bar and coil form are given in Table 1.

Table 1 Common commercially available sizes of cold-finished steel bars and coils

Configuration	Bars ^(a)								Coils ^(b) , sizes

Product Types

In the manufacture of cold-finished bars, the steel is first hot rolled oversize to appropriate shape and is then subjected to mechanical operations (other than those intended primarily for scale removal) that affect its machinability, straightness, and end-cut properties. The two common methods of cold finishing bars are:

- Removal of surface material by turning or grinding, singly or in combination
- Drawing the material through a die of suitable configuration

Pickling or blasting to remove scale may precede turning or grinding and must always precede drawing. For bar products, cold rolling has been almost superseded by cold drawing. Nevertheless, cold-finished bars and special shapes are sometimes incorrectly described as cold rolled.

Commercial Grades. Any grade of carbon or alloy steel that can be hot rolled can also be cold finished. The choice of grade is based on the attainable cold-finished and/or hardenability and tempering characteristics necessary to obtain the required mechanical properties.

Production methods vary widely among cold-finished cold-drawn suppliers. For example, one supplier currently anneals and cold draws grades 1070, 1090, and 5160, and in the future plans to do the same with grade 9254. Grade 1070 is a high-volume item, and cold drawing is required for precision sizing and subsequent nondestructive testing of the bar, using a rotating-probe eddy current device (see the articles "Eddy Current Inspection," "Remote-Field Eddy Current Inspection," and "Steel Bar, Wire, and Billets" in *Nondestructive Evaluation and Quality Control*, Volume 17 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*) for detecting surface seams. Cold drawing is also necessary because the smallest hot-rolled size typically available for some applications is not small enough for customer use. Thus, a supplier whose smallest hot-rolled bar size is 11.1 mm (0.437 in.) cold draws this diameter to as small as 9.98 mm (0.393 in.).

Carbon steels containing more than 0.55% C must be annealed prior to being cold drawn so that the hardness will be sufficiently low to facilitate the cold-drawing operation. For carbon steels containing up to 0.65% C, this will normally be a lamellar pearlitic anneal; for carbon steels containing more than 0.65% C, a spheroidize anneal is required. The type of structure required is normally reached by agreement between the steel producer and the customer.

Alloy steels containing more than 0.38% C are usually annealed before cold drawing.

Machined Bars. Bar products that are cold finished by stock removal can be:

- Turned and polished
- Turned, ground, and polished

- Cold drawn, ground, and polished
- Cold drawn, turned, and polished
- Cold drawn, turned, ground, and polished

Turning is done in special machines with cutting tools mounted in rotating heads, thus eliminating the problem of having to support long bars as in a lathe. Grinding is done in centerless machines. Polishing can be done in a roll straightener of the crossed-axis (Medart) type with polished rolls to provide a smooth finish. Polishing by grinding with an organic wheel or with a belt is of increasing interest (see the article "Grinding Equipment and Processes" in *Machining*, Volume 16 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*) because it is cost effective to grind and polish the bars on the same machine simply by using grinding wheels or belts of different grit size. Grinding produces a smoother finish than turning; polishing improves the surface produced by either technique. Turned, ground, and polished rounds represent the highest degree of overall accuracy, concentricity, straightness, and surface perfection attainable in commercial practice (Ref 3).

The surface finish desired is specified by using the process names given above because the industry has not developed standard numerical values for roughness, such as microinch or root mean square (rms) numbers. However, surface finish with respect to rms (root mean square deviation from the mean surface) as determined with a profilometer can be negotiated between the producer and a customer. This could be done for such critical-finish applications as turned and polished bars used to produce shafting as well as stock used to produce machined parts of which a superior finish is required on surfaces not machined.

The published range of diameters both for turned and for turned and ground bars is 13 to 229 mm ($\frac{1}{2}$ to 9 in.) inclusive; for cold-drawn and ground bars, it is 3.2 to 102 mm ($\frac{1}{8}$ to 4 in.) inclusive. These are composites of size ranges throughout the industry; an individual producer may be unable to furnish a full range of sizes.

For example, one well-known producer supplies turned rounds from 13 to 229 mm ($\frac{1}{2}$ to 9 in.), another from 29 to 203 mm ($1\frac{1}{8}$ to 8 in.)--all finished sizes. Yet another producer supplies sizes up to and including 152 mm (6 in.) that are turned on special turning machines and ground on centerless grinders; larger sizes are lathe turned and ground on centers. Because turning and grinding do not alter the mechanical properties of the hot-rolled bar, this product can be machined asymmetrically with practically no danger of warpage (Ref 3).

Stock removal is usually dependent on American Iron and Steel Institute (AISI) seam allowances (Ref 2). Stock removal in turning, or turning and grinding, measured on the diameter, is normally 1.6 mm ($\frac{1}{16}$ in.) for sizes up to 38 mm ($1\frac{1}{2}$ in.), 3.2 mm ($\frac{1}{8}$ in.) for the 38 to 76 mm ($1\frac{1}{2}$ to 3 in.) range, 4.8 mm ($\frac{3}{16}$ in.) for the 76 to 127 mm (3 to 5 in.) range, and 6.4 mm ($\frac{1}{4}$ in.) for 127 mm (5 in.) diameter and larger.

Cold-drawn round bars are available in a range of diameters from 3.2 to 152 mm ($\frac{1}{8}$ to 6 in.). The maximum diameters available from individual producers, however, may vary from 76 to 152 mm (3 to 6 in.). The reduction in diameter in cold drawing, called draft, is commonly 0.79 mm ($\frac{1}{32}$ in.) for finished sizes up to 9.5 mm ($\frac{3}{8}$ in.) and 1.6 mm ($\frac{1}{16}$ in.) for sizes over 9.5 mm ($\frac{3}{8}$ in.). Some special processes use heavier drafts followed by stress relieving. One producer employs heavy drafting at elevated temperature. With this exception, drawing operations are begun with the material at room temperature to start, and the only elevated temperature involved is that developed in the bar as a result of drawing; this temperature rise is small and of little significance.

Originally, cold finishing, whether by turning or by cold rolling, was employed only for sizing to produce a bar with closer dimensional tolerances and a smoother surface. As cold-finished bar products were developed and improved, increased attention was paid to the substantial enhancement of mechanical properties that could be obtained by cold working. This additional advantage is now more fully appreciated, as evidenced by the fact that increased mechanical properties are an important consideration in about 40% of the applications. In approximately half of these applications, or 20% of the total, cold drawing is used only to increase strength; in the other 20%, close tolerances and better surface finish are desired in addition to increased strength.

As-rolled microalloyed high-strength low-alloy (HSLA) steels or microalloyed HSLA steels in various combinations of controlled drafting and furnace treatment provide an extension of property attainment. A high percentage of free-machining steels are cold drawn for the combination of size accuracy and improved machinability. Recent developments in microalloyed steels provide hot-rolled turned bars, under certain circumstances, having mechanical properties similar to cold-drawn nonmicroalloyed steels.

An appreciable fraction of all applications of cold finishing to carbon steel bars utilizes cold drawing to improve mechanical properties. For alloy steel, however, cold finishing is commonly used to improve surface finish and dimensional accuracy, and not for additional mechanical strength. When additional mechanical strength is desired, alloy steel bars may be heat treated (quenched and tempered) and then cold drawn and stress relieved. Elevated-temperature or warm-drawn steels are also available with increased mechanical strength and improved machinability.

Heavily drafted and strain-tempered carbon and alloy steels subjected to induction hardening of the surface provide many additional property combinations. The extra cost of using alloy steel in cold-finished bars can be justified only when heat treatment (quenching and tempering) is necessary for meeting the required strength level. Because work-hardening effects are removed during heating prior to quenching, the benefit of increased mechanical strength due to cold finishing is eliminated from the finished product.

Turning Versus Cold Drawing. Basic differences exist between bars finished by turning and those finished by cold drawing. First, it is obvious that turning and centerless grinding are applicable only to round bars, while drawing can be applied to a variety of shapes. Drawing, therefore, is more versatile than turning.

Second, there is a difference in the number and severity of the surface imperfections that may be present. Because stock is removed in turning and grinding, shallow surface imperfections and decarburization may be completely eliminated. When material is drawn, stock is only displaced, and surface imperfections are only reduced in depth (in the ratio of the change in bar diameter or section thickness). The length of these imperfections may be slightly increased because in the drawing operation an increase in length accompanies the reduction in cross section.

Cold-drawn bars can approach the freedom from surface imperfections obtained in turned or turned and ground bars if the hot-rolled bars from which they are produced are rolled from specially conditioned billets. Quality conditions such as cold-working quality are available from producers of hot-rolled bars. The depth limits of the surface imperfections are as agreed to between the producer and the customer. However, if maximum freedom from surface imperfections is the controlling factor, turned bars have an advantage.

Different size tolerances are applicable to cold-finished products, depending on shape, carbon content, and heat treatment. Listed in Tables 2, 3, and 4 are the tolerances for cold-finished carbon and alloy steel bars published in ASTM A 29. These tables include cold-drawn bars; turned and polished rounds; cold-drawn, ground, and polished rounds; and turned, ground, and polished rounds. From the data in Tables 2, 3, and 4, certain generalizations can be stated. The tolerances for cold-drawn and for turned and polished rounds, for example, are the same for sizes up to and including 102 mm (4 in.). There are differences, however, between the tolerances that apply to carbon steel and those that apply to alloy steels. Tolerances for several finishes also vary with certain levels of carbon content. Broader tolerances are applicable to bars that have been heat treated before cold finishing. In contrast, tolerances are closer when bars are ground, and these tolerances are independent of carbon content.

Table 2 Size tolerances for cold-finished carbon steel bars, cold drawn or turned and polished

This table includes tolerances for bars that have been annealed, spheroidize annealed, normalized, normalized and tempered, or quenched and tempered before cold finishing. This table does not include tolerances for bars that are annealed, spheroidize annealed, normalized, normalized and tempered, or quenched and tempered after cold finishing; the producer should be consulted for tolerances for such bars.

Size		Size tolerance									
		Maximum carbon (C) range, %								All grades quenched and tempered or normalized before cold finishing	
		C ≤ 0.28		0.28 < C ≤ 0.55		C ≤ 0.55 including stress relief or annealed after cold finishing		C > 0.55

- (a) Tolerances can be ordered all plus, or distributed plus and minus with the sum equivalent to the tolerances listed.
- (b) Width governs the tolerance for both width and thickness of flats, for example, when the maximum of carbon range is 0.28% or less for a flat 50 mm (2 in.) wide and 25 mm (1 in.) thick. The width tolerance is 0.13 mm (0.005 in.), and the thickness is the same, nearly 0.13 mm (0.005 in.).

Table 3 Size tolerances for cold-finished alloy steel bars, cold drawn or turned and polished

This table includes tolerances for bars that have been annealed, spheroidize annealed, normalized, normalized and tempered, or quenched and tempered before cold finishing. This table does not include tolerances for bars that are annealed, spheroidize annealed, normalized, normalized and tempered, or quenched and tempered after cold finishing; the producer should be consulted for tolerances for such bars.

Size		Size tolerance

(a) For nonresulfurized steels (steels specified to maximum sulfur limits under 0.08% or for steels thermally treated, the tolerance is increased by 0.03 mm (0.001 in.).

In addition to the size-tolerance requirements for all cold-finished steel bars, straightness tolerances are also of major importance for bars intended for use in automatic screw machines. Table 5 (also from ASTM A 29) details the straightness requirements for rounds, squares, hexagons, and octagons, which are the same for both carbon and alloy steel bars. As indicated in Table 6, special provisions are also made for bars subject to magnetic particle inspection.

Table 5 Straightness tolerances for cold-finished carbon and alloy steel bars

All grades quenched and tempered or normalized and tempered to \leq HB 302 before cold finishing; all grades stress relieved or annealed after cold finishing. Straightness tolerances are not applicable to bars having Brinell hardness exceeding 302. The tolerances are based on the following method of measuring straightness. Departure from straightness is measured by placing the bar on a level table so that the arc or departure from straightness is horizontal, and the depth of the arc is measured with a feeler gage and a straightedge.

It should be recognized that straightness is a perishable quality and may be altered by mishandling. The preservation of straightness in cold-finished bars requires the utmost care in subsequent handling. Specific straightness tolerances are sometimes required for carbon and alloy steels, in which case the purchaser should inform the manufacturer of the straightness tolerances and the methods to be used in checking the straightness.

Size		Length		Straightness tolerances (maximum deviation) from straightness in any 3 m (10 ft) portion of the bar							
				Carbon range, $\leq 0.28\%$				Carbon range $>0.28\%$ and all grades thermally treated

Table 6 Minimum stock removal for cold-finished steel bars subject to magnetic particle inspection

For turned and polished alloy steel bars subject to magnetic particle inspection, the recommended minimum total stock removal from the surface (the amount removed by the producer plus the amount removed by the purchaser) is based on the hot-rolled alloy steel bar size used by the producer.

Cold-finished size		Minimum stock removal from the surface ^(a)	
mm	in.	mm	in.
To 11.1 incl	To $\frac{7}{16}$ incl	0.76	0.030
>11.1-17.5 incl	$>\frac{7}{16}$ - $\frac{11}{16}$ incl	1.14	0.045

Product Quality Descriptors

The term quality relates to the suitability of a mill product to become an acceptable part. When used to identify cold-finished steel bars, the various quality descriptors are indicative of many characteristics, such as degree of internal soundness, relative uniformity of chemical composition, and relative freedom from detrimental surface imperfections.

Because of the characteristic surface finish of cold-drawn bars, close visual inspection cannot identify detrimental surface imperfections. Therefore, for applications that do not allow surface imperfections on the finished surfaces of standard quality cold-drawn carbon steel bars and regular quality cold-drawn alloy steel bars, the user should recognize that some stock removal is necessary to eliminate such imperfections as seams. The recommended stock removal per side for all nonresulfurized grades is 0.025 mm (0.001 in.) per 1.6 mm ($\frac{1}{16}$ in.) of cross section, or 0.25 mm (0.010 in.), whichever is greater. For example, for a 25 mm (1 in.) bar, recommended stock removal is 0.41 mm (0.016 in.) per side. For the resulfurized grades, recommended stock removal is 0.038 mm (0.0015 in.) per 1.6 mm ($\frac{1}{16}$ in.), or 0.38 mm (0.015 in.), whichever is greater. Therefore, for a 25 mm (1 in.) bar, recommended stock removal is 0.61 mm (0.024 in.) per side.

Occasionally, some bars in a shipment may have imperfections that exceed the recommended stock removal limits. Therefore, for critical applications, inspection of finished parts is recommended, or more restrictive quality and/or additional inspection methods can be specified by agreement of both supplier and customer.

To minimize pitting, the recommended stock removal per side for cold-drawn bars that are to be decorative chromium plated is as follows:

Size, mm (in.)	Stock removal per side, mm (in.)
Through 7.9 ($\frac{5}{16}$)	0.15 (0.006)
Over 7.9 ($\frac{5}{16}$) through 11.1 ($\frac{7}{16}$)	0.20 (0.008)
Over 11.1 ($\frac{7}{16}$)	0.25 (0.010)

Carbon Steel Quality Descriptors

Standard quality is the descriptor applied to the basic quality level to which cold-finished carbon steel bars are produced. Standard quality cold-finished bars are produced from hot-rolled carbon steel of special quality (the standard quality for hot-rolled bars for cold finishing). Steel bars of standard quality must be free from visible pipe and excessive chemical segregation. They may contain surface imperfections. In general, the size of surface imperfections increases with bar size.

Restrictive requirement quality A (RRA) incorporates all the features of standard quality carbon steel bars described above, plus any one of the following restrictive requirements.

Special surface bars are produced with special surface preparation to minimize the frequency and size of seams and other surface imperfections. These bars are used for applications in which machining allowances do not allow sufficient surface removal to clean up the detrimental imperfections that occur in standard quality bars.

Special internal soundness bars have greater freedom from chemical segregation and porosity than standard quality bars.

Special hardenability bars are produced to hardenability requirements other than those of standard H-steels.

Cold-finished carbon steel bars are also produced to inclusion ratings as determined by standard nonmetallic inclusion testing.

Restrictive requirement quality B (RRB) incorporates all the features of standard quality carbon steel bars, plus any one of the following.

Special discard is specified when minimized chemical segregation, special steel cleanliness, or internal soundness requirements dictate that the product be selected from certain positions in the ingot.

Minimized decarburization is specified whenever decarburization is important, as in heat treating for surface hardness requirements.

Single restrictions other than those noted above, such as special chemical limitations, special processing techniques, and other special characteristics not previously anticipated, are also covered by this quality level.

Multiple restrictive requirement quality (MRR) applies when two or more of the above-described restrictive requirements are involved.

Cold-forging quality A and cold-extrusion quality A apply to cold-finished carbon steel bars used in the production of solid or hollow shapes by means of cold plastic deformation involving the movement of metal by compression with no expansion of the surface and not requiring special inspection standards. For an individual application, if the type of steel or chemical composition specified does not provide adequate cold-forming characteristics in the as-drawn condition, a suitable heat treatment to provide proper hardness or microstructure may be necessary.

Cold-heading quality, cold-extrusion quality B, cold-upsetting quality, and cold-expansion quality apply to cold-finished carbon steel bars used in production of solid or hollow shapes by means of severe cold plastic deformation by cold heading, cold extrusion, cold upsetting, or cold expansion involving movement of metal by expansion and/or compression. Such bars are obtained from steel produced by closely controlled steelmaking practices and are subject to special inspection standards for internal soundness and surface quality and uniform chemical composition. For grades of steel with a maximum specified carbon content of 0.30% or more, an anneal or spheroidize anneal heat treatment may be required to obtain the proper hardness and microstructure for cold working.

Restrictive cold-working quality applies to cold-finished carbon steel bars used in the production of solid or hollow shapes by means of very severe cold plastic deformation involving cold working by expansion and/or compression. This degree of cold working normally involves restrictive inspection standards and requires steel that is exceptionally sound, of uniform chemical composition, and virtually free of detrimental surface imperfections. Such severe cold-forming operations normally require suitable heat treatment to obtain proper hardness and microstructure for cold working.

Other Carbon Steel Qualities. The quality descriptors listed below are some of those that apply to cold-finished carbon steel bars intended for specific requirements and applications. They may have requirements for surface quality, amount of discard, macroetch tests, mechanical properties, or chemical uniformity as indicated in product specifications:

- Axle shaft quality
- Shell steel quality A
- Shell steel quality C
- Rifle barrel quality
- Spark plug quality

Alloy Steel Quality Descriptors

Regular quality is the descriptor applied to the basic, or standard, quality level to which cold-finished alloy steel bars are produced. Steels for this quality are killed and are usually produced to a fine grain size. They are melted to chemical ranges and limits and are inspected and tested to meet normal requirements for regular constructional alloy steel applications. Regular quality cold-finished alloy steel bars may contain surface imperfections to the depths mentioned in the opening paragraphs of the section "Product Quality Descriptors" in this article. In general, the size of detrimental surface imperfections increases with bar size.

Cold-heading quality applies to cold-finished alloy steel bars intended for applications involving cold plastic deformation by such operations as upsetting, heading, or forging. Bars are supplied from steel produced by closely controlled steelmaking practices and are subject to mill testing and inspection designed to ensure internal soundness, uniformity of chemical composition, and freedom from detrimental surface imperfections. Proper control of hardness and microstructure by heat treatment and cold working is important for cold forming. Most cold-heading quality alloy steels are low- and medium-carbon grades. Typical low-carbon alloy steel parts, made by cold heading, include fasteners (cap screws, bolts, eyebolts), studs, anchor pins, and rollers for bearings. Examples of medium-carbon alloy steel cold-headed parts are bolts, studs, and hexagon-headed cap screws.

Special cold-heading quality applies to cold-finished alloy steel bars for applications involving severe cold plastic deformation when slight surface imperfections may cause splitting of a part. Bars of this quality are produced by closely controlled steelmaking practices to provide uniform chemical composition and internal soundness. Also, special processing (such as grinding) is applied at intermediate stages to remove detrimental surface imperfections. Proper control of hardness and microstructure by heat treatment and cold working is important for cold forming. Typical applications of alloy steel bars of this quality are front suspension studs, socket screws, and some valves.

Axle shaft quality applies to cold-finished alloy steel bars intended for the manufacture of automotive or truck-type, power-driven axle shafts, which by their design or method of manufacture are either not machined all over or undergo less than the recommended amount of stock removal for proper cleanup of normal surface imperfections. Axle shaft quality bars require special rolling practices, special billet and bar conditioning, and selective inspection techniques.

Ball and roller bearing quality and bearing quality apply to cold-finished alloy steel bars used for the manufacture of antifriction bearings. Such bars are usually produced from alloy steels of the AISI-SAE standard alloy carburizing grades and the AISI-SAE high-carbon chromium series. These steels can be produced in accordance with ASTM A 534, A 295, and A 485. Bearing quality steels are subjected to restricted melting and special teeming, heating, rolling, cooling, and conditioning practices to meet rigid quality requirements. The steelmaking operations may include vacuum treatment. The foregoing requirements include thorough examination for internal imperfections by one or more of the following methods: macroetch testing, microscopic or ultrasonic examination for nonmetallic inclusions, and fracture testing.

Aircraft quality and magnaflux quality apply to cold-finished alloy steel bars for important or highly stressed parts of aircraft and for other similar or corresponding purposes involving additional stringent requirements, such as magnetic particle inspection, additional discard, macroetch tests, and hardenability control. To meet these requirements, exacting steelmaking, rolling, and testing practices must be employed. These practices are designed to minimize detrimental inclusions and porosity. Phosphorus and sulfur are usually limited to 0.025% maximum. There are many aircraft parts and many parts for missiles and other rockets that require aircraft quality steel. The magnetic particle testing requirements given in AMS 2301 are sometimes specified for such applications.

Other Alloy Steel Qualities. The quality descriptors listed below apply to cold-finished alloy steel bars intended for rifles, guns, shell, shot, and similar applications. They may have requirements for amount of discard, macroetch testing, surface requirements, or magnetic particle testing as indicated in the product specifications:

- Armor-piercing (AP) shot quality
- AP shot magnaflux quality
- Gun quality
- Rifle barrel quality
- Shell quality
- Shell magnaflux quality

Mechanical Properties

A major difference between machined and cold-drawn round bars is the improvement in tensile and yield strengths that results from the cold work of drawing. Cold work also changes the shape of the stress-strain diagram, as shown in Fig. 1. Within the range of commercial drafts, cold work markedly affects certain mechanical properties (Fig. 2). The variations in percentage of reduction of cross section for bars drawn with normal commercial drafts of 0.8 and 1.6 mm ($\frac{1}{32}$ and $\frac{1}{16}$ in.) and with heavy drafts of 3.2 and 4.8 mm ($\frac{1}{8}$ and $\frac{3}{16}$ in.) are shown in Fig. 3. Normal reductions seldom exceed 20% and are usually less than 12%. According to Fig. 2, the more pronounced changes in significant tensile properties occur within this range of reductions (up to about 15%).

Fig. 1 Effect of cold work on the tensile stress-strain curve for low-carbon steel bars

Fig. 2 Effect of cold drawing on the tensile properties of steel bars. Data are for bars up to 25 mm (1 in.) in cross section having a tensile strength of 690 MPa (100 ksi) or less before cold drawing.

Fig. 3 Effect of draft on reduction of cross section of steel bars

The minimum mechanical properties of several cold-drawn carbon steel bars in a range of sizes are presented in Table 7. In addition, the effects of both low- and high-temperature stress relief on the as-cold-drawn mechanical properties are noted. The mechanical property ranges and average values for one of the steels listed in Table 7 (1137 resulfurized steel) are presented in Fig. 4, which also shows the advantage in strength of cold-drawn over hot-rolled material.

Table 7 Estimated minimum mechanical properties of cold-drawn carbon steel rounds, squares, and hexagons

Estimated minimum mechanical properties for sizes under 16 mm ($\frac{5}{8}$ in.) can be obtained from individual producers. The data in this table are not applicable to turned and polished or turned and ground bars, which have mechanical properties corresponding to those of hot-rolled steel bars of the same size and grade. The size of a square or hexagon is the distance between opposite sides.

Fig. 4 Mechanical properties of hot-rolled and cold-drawn 1137 bars

Measurements of the changes in mechanical properties of three specific carbon steels (1016, 1040, and 1060) and one alloy steel (8630) as a result of cold-drawing are shown in Fig. 5, 6, 7, and 8. Some of these data pertain to large reductions, well beyond commercial ranges. Data plotted as solid lines in Fig. 5, 6, 7, and 8 are for bars that were cold drawn and artificially aged, but not stress relieved. After drawing, these bars were aged for 4 h at 100 °C (212 °F) to simulate the natural aging resulting from several months of storage at room temperature. Data plotted as dashed lines in Fig. 5, 6, 7, and 8 are for cold-drawn and stress-relieved bars; carbon steels were stress-relieved for 2 h at 480 °C (900 °F), and 8630 steel for 2 h at 540 °C (1000 °F), after cold drawing.

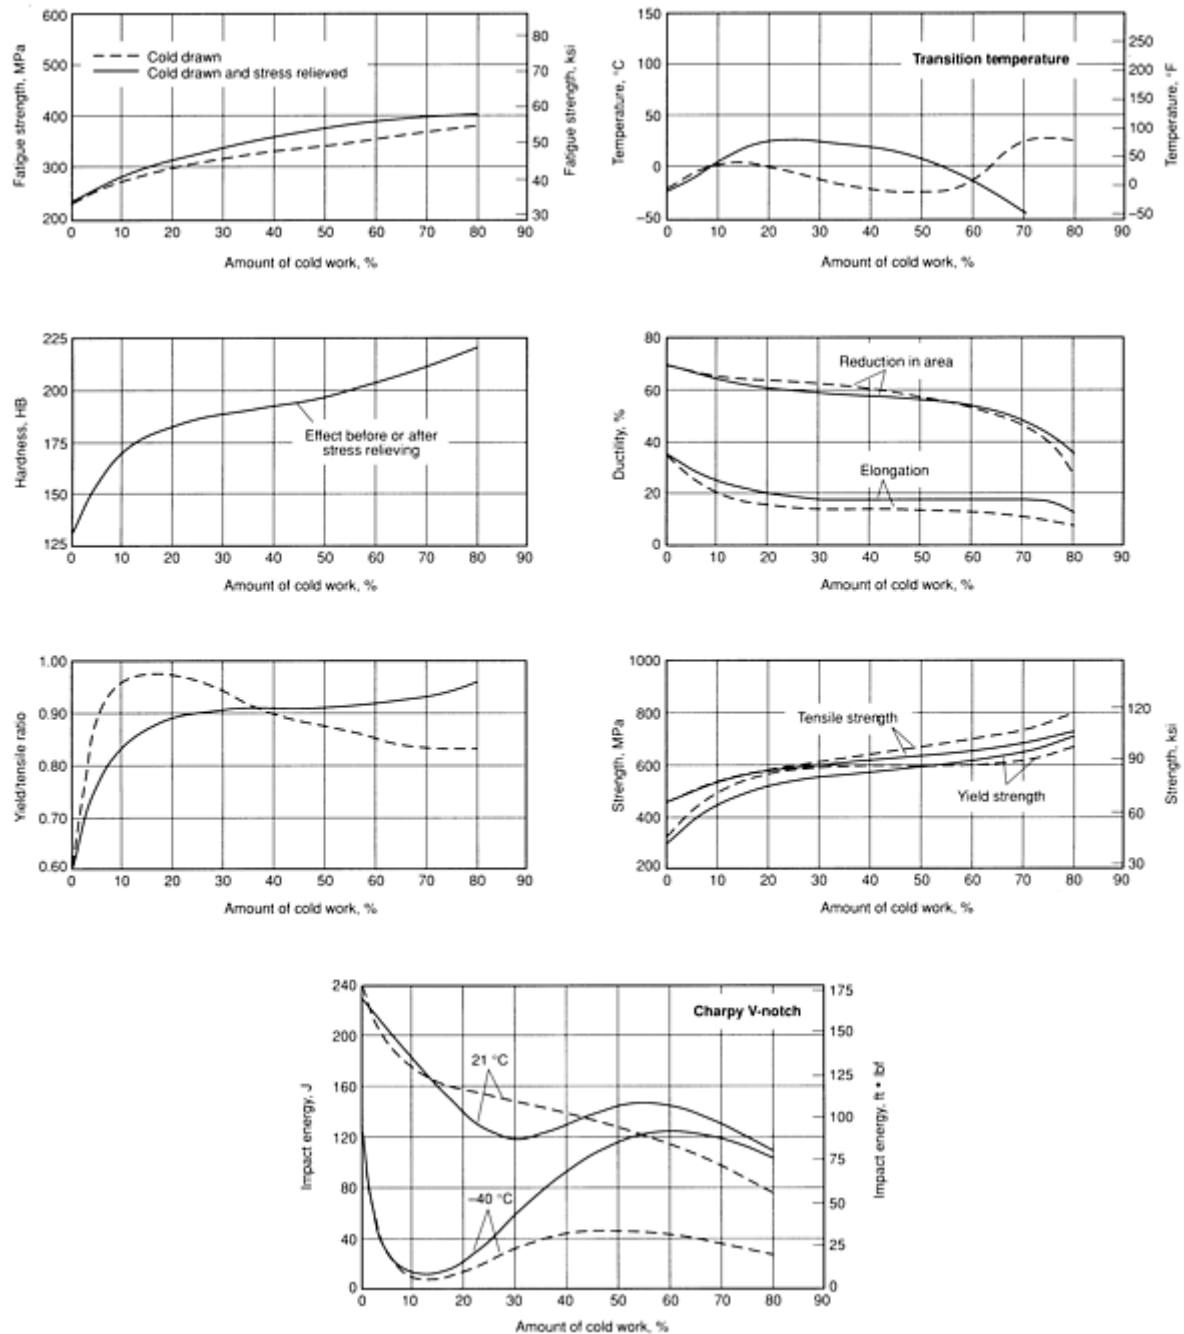

Fig. 5 Effects of cold drawing and of cold drawing and stress relieving on mechanical properties of 1016 steel bars. Dashed curves represent cold-drawn material; solid curves, material cold drawn and stress relieved. All bars were from a single heat. The bars were hot reduced to a diameter of 51 mm (2 in.) by conventional practice, then normalized and cold drawn to the reductions indicated. Note that the larger reductions are well beyond commercial ranges. Test specimens were taken from half-radius positions in the bars. The bars that were stress relieved after cold drawing were treated as follows: carbon steel bars, 2 h at 480 °C (900 °F); 8630 bars, 2 h at 540 °C (1000 °F). All bars were aged for 4 h at 100 °C (212 °F) after cold drawing, or after cold drawing and stress relieving, to simulate the condition of steel after several months of storage at room temperature. Tensile and Yield Strengths. The data in Fig. 2, 5, 6, 7, and 8 indicate that as cold work increases up to about 15%, yield strength increases at a greater rate than tensile strength. The greatest improvement in strength results from the first 5% of reduction. Stress relieving modifies this pattern appreciably. They yield/tensile ratio is markedly affected by cold drawing. In this condition (cold drawn, not stress relieved; see Fig. 5, 6, 7, and 8), the data for yield/tensile ratio indicate a

somewhat erratic behavior. However, the ratio follows a consistent upward trend with increased cold work and subsequent stress relief.

The hardness increases with increased cold work and, in most cases, is affected by stress relieving. There is considerable scatter in the relations between hardness and tensile strength and hardness and yield strength, as indicated by the data in Fig. 9 for 41 heats of cold-drawn and stress-relieved 1144 steel. However, there is a relationship between hardness and tensile strength or hardness and yield strength, because published tables allow approximation of the hardness or tensile strength (or yield strength) when one of the other values is known.

Fig. 9 Mechanical properties of 1144 steel bars cold drawn and stress relieved at 565 °C (1050 °F). Range of

composition for 41 heats was 0.41 to 0.52% C, 1.33 to 1.68% Mn, and 0.220 to 0.336% S.

Impact Properties. Available data are limited on the effect of cold work on notched-bar impact properties. The results of one of the more important studies are included in Fig. 5, 6, 7, and 8, which show the effect of cold work over a wide range of drafts on three carbon steels with increasing carbon contents and the effect of cold work on 8630 alloy steel. Within the range of commercial drafts, energy absorbed (breaking strength) falls rapidly for the 1016 steel and less rapidly for 8630 steel. At any level of cold work, energy absorbed decreases with increased carbon content.

In the stress-relieved condition, the fracture transition temperature generally rises with increasing amounts of cold work up to 20 to 30% reduction. Beyond this commercial range of reductions, the transition temperature falls. For 1016 steel, extremely heavy drafts lower the transition temperature to below that of the original hot-rolled material. Increasing carbon content raises the transition temperature.

Residual Stresses

The stress pattern produced by cold drawing depends on the amount of reduction and the shape of the die, as well as the microstructure, hardness, and grade of steel. Figure 10 illustrates the effect of reduction in area on the magnitude and distribution of stresses in bars of 1050 steel reduced by the amounts shown. Cold drawing of the bars to 4.1% reduction resulted in surface compressive stresses, while increasing the amount of cold drawing to 12.3% reduction resulted in a change of the surface stresses from compressive to tensile. The variation in longitudinal stress over a much wider range of reduction values is shown in Fig. 11 for steel wire (the effect is qualitatively similar for bars). The greatest effect on the residual stress is caused by the first 10% reduction. The effect of a very light draft is to produce compressive stress at the surface, which rapidly changes to tensile stress with a relatively small increase in reduction.

Fig. 11 Effect of increasing single-draft reduction on residual longitudinal stress at the surface of drawn steel wire

Both straightening and stress relieving after cold drawing have significant effects on the residual stress pattern of the resulting product. Figure 12 shows the longitudinal, tangential, and radial stress patterns that result when a 43 mm ($1\frac{11}{16}$ in.) diam carbon steel bar is drawn to 38 mm ($1\frac{1}{2}$ in.), a reduction of 20%. These data indicate that the surface of the bar is in tension, the center is in compression, and both longitudinal and tangential stresses vary over wide ranges.

Fig. 12 Residual stress patterns obtained in cold-drawn steel bars of 1045 steel. (a) As-drawn. (b) After rotary straightening. (c) After stress relieving. Bars were cold drawn 20% from 43 to 38 mm ($1\frac{11}{16}$ to $1\frac{1}{2}$ in.).

Straightening in a skewed-rolls (Medart) machine significantly reduces residual stress, particularly at the surface, as shown in Fig. 12(b). It is of interest to compare the longitudinal stress curve shown in Fig. 12(b) with that in Fig. 12(a). Figure 12(c) shows the effect of two stress-relieving temperatures (425 and 540 °C, or 800 and 1000 °F) on residual longitudinal stress. Stress relieving at these temperatures is only slightly more effective than straightening in reducing the residual stress level. This phenomenon may be accounted for by an analysis of the nature of the stresses that are developed in cold drawing.

The stress applied in cold drawing is sufficient to deform the material both elastically and plastically. Because the initiation of plastic strain depends on the development of maximum elastic strain, the ratio of these two strains after

release of the deforming stress may be highly variable. If the deformation caused by cold drawing were uniform across the section, as in pure stretching, the elastic stress would be released by the release of the deforming stress. Because the plastic strain is not uniform, as shown by the dishing of the ends of drawn bars, neither is the accompanying elastic strain. When the deforming stress is removed from such a system, the remaining nonuniform elastic-strain energy cannot be released completely, because the resistance of low-strain regions prevents the complete recovery of regions of high strain. A pattern of residual stress results from this unequal adjustment.

Stress Relieving. The inevitable residual stresses in as-drawn bars can be relieved mechanically or thermally (Ref 7). Mechanical relief may take two forms. One involves the introduction of stresses of opposite sign, which can be accomplished by shot peening. A second approach is to plastically deform the material further, thus affording additional opportunity for the relief of non-uniform residual stresses. The data on rotary straightening in Fig. 12(b) demonstrate this effect.

The thermal stress relieving of cold-drawn bars--also known as strain drawing, strain annealing, strain relieving, preaging, and stabilizing--is probably the most widely used thermal treatment applied to cold-drawn bars. Its purpose is to modify the magnitude and distribution of residual stresses in the cold-finished bar and thus produce a product with the desired combination of mechanical properties for field service. Thermal stress relief temporarily reduces the strength level of the material (at the stress-relieving temperature) and enables the elastic-strain energy to find release in small but significant amounts of plastic deformation. After stress relieving, the maximum residual stress that can remain is equal to the yield strength of the material at the stress-relieving temperature.

Temperatures up to about 650 °C (1200 °F) are commonly used for the stress relieving of cold-drawn bars. The upper limit for the stress-relief temperature for a particular cold-worked steel is the recrystallization or lower critical temperature of that steel, because if this temperature is exceeded, the strengthening effect of cold work is lost. The temperatures used in commercial practice frequently range from 370 to 480 °C (700 to 900 °F). When stress relieving is performed at relatively low temperatures (for example, 290 °C, or 550 °F), yield strength of most cold-drawn steels is increased. At higher temperatures, however, hardness, tensile strength, and yield strength are reduced, while elongation and reduction in area are increased. The choice of a specific time and temperature is dependent on chemical composition, cold-drawing practice, and the final properties required in the bar.

The various categories of stress relief can be divided into three groups:

- *Group 1:* Complete relief of all cold-working stresses
- *Group 2:* Relief of cold-working stresses to a limited degree to increase ductility and stability in the material
- *Group 3:* Relief of stresses in heavily drafted steels to develop high yield strength

Group 1 treatment is conducted above 540 °C (1000 °F). It removes all residual stresses that otherwise would cause objectionable distortion in machining.

Group 2 Treatment. With group 2 processing, lower temperatures in the range of 370 to 540 °C (700 to 1000 °F) are used, and the stresses are partially relieved to bring the mechanical properties within the limits of individual specifications. Applications falling into this class are those that may require ductility close to that of hot-rolled steel, along with good surface finish and close control of dimensions and stability during machining.

Group 3 stress relief is used for bars with heavy drafts. These drafts raise the tensile and yield strengths to high levels, but reduce elongation and reduction in area. Heating to 260 to 425 °C (500 to 800 °F) restores the ductility while retaining or increasing the strength and hardness imparted by the cold work.

The effect of stress relieving at two temperatures on the residual stress pattern of 38 mm (1.5 in.) diam 0.45% C steel bars that have been cold drawn 20% is shown in Fig. 12. The estimated minimum mechanical properties for cold-drawn carbon steel bars as-cold-drawn and as-cold-drawn followed by both a low- and a high-temperature stress-relieving treatment are given in Table 7. The cumulative effects of cold drawing, straightening, and stress relieving on the yield and tensile strength of 1144 steel are shown in Fig. 13.

Heat Treatment

Heat treatment by quenching and tempering, followed by scale removal and then cold drawing, can also be used as a method of producing stronger cold-finished bars in those grades amenable to quench hardening. Heat treatment provides the required increase in strength, and cold drawing provides the size and finish, with a minimal increase in the mechanical properties obtained by quench hardening. Alternatively, quenched and tempered bars can be cold finished by turning and polishing. When bars are cold finished by turning and polishing, there is no increase in the mechanical properties obtained by quench hardening.

For the cold drawing of quenched and tempered bars to be economically justifiable, the minimum strength level produced must be above that obtainable by conventional cold-drawn practices. The upper strength limit is not clearly defined, but for most applications it is the upper limit of machinability. The cold drawing of quenched and tempered bars is applicable to both carbon and alloy steels; however, for the process to be economically justifiable, alloy steel is used only in those sizes above which carbon steel will not respond satisfactorily to liquid quenching. Typically, quenched and tempered product offers superior ductility and heat-resistant properties. Other heat treatments--principally normalizing, full annealing, spheroidizing, and thermal stress relieving--can be applied to suitable grades of hot-rolled steel before or after cold drawing or turning and polishing as required by the end product.

Control of microstructure is frequently important, a good example being annealing for machinability. A controlled rate of continuous cooling through the pearlite transformation range (so-called cycle annealing) is employed. Isothermal cycles are also used. In the cycle-annealing process, the rate of cooling of the furnace charge is adjusted so that the time required to traverse the pearlite temperature interval is sufficient to allow completion of that transformation. By regulating the dwell in the transformation temperature range, the carbide distribution in the product can be varied from partly spheroidal to fully pearlitic, and the pearlite from coarse to fine. In this manner, the optimum machining structure can be obtained for the grade and the machining practice being used.

Spheroidize annealing thermal treatment is given to cold-finished bars that are to be used for severe cold-forming operations. The aim of this treatment is to develop a microstructure consisting of globular carbides in a ferrite matrix. The rate of spheroidizing depends to some degree on the original microstructures. Prior cold work also increases the rate of spheroidizing, particularly for subcritical spheroidizing treatments.

The spheroidized structure is desirable when minimum hardness and maximum ductility are important. Low-carbon steels are seldom annealed for machining because, in the annealed condition, they are very soft and gummy, which tends to produce long, stringy chips that cause handling problems at the machine tool and contribute to a rough surface finish on the machined part. When such steels are spheroidized, it is usually to permit severe cold deformation.

Carbon Restoration. During the hot-working operations involved in the production of bar products--the reduction of cast ingots, blooms, or billets and subsequent conversion in bar mills--decarburization of the bar surface takes place because of exposure to ambient oxygen at high temperatures throughout these operations. A specialized variant of full annealing, called carbon restoration or carbon correction, is utilized to compensate for the loss of carbon due to decarburization.

Carbon restoration for alloy steels is limited because vanadium carbide and molybdenum are not recovered. By heating the descaled hot-rolled bars to approximately 870 to 925 °C (1600 to 1700 °F) in a controlled atmosphere, it is possible to restore surface carbon to the required level. A modern controlled-atmosphere furnace is used for this purpose. Methane or other light hydrocarbons are burned with a controlled amount of air in an endothermic generator to produce a gas with a mixed ratio of CO to CO₂. By controlling the CO/CO₂ ratio of the endothermic gas, an atmosphere can be generated that will be in equilibrium with the carbon content of the steel to be treated. Low-ratio gas is in equilibrium with lower-carbon steels, and high-ratio gas is in equilibrium with higher content steels. The actual ratio used depends on the type of anneal and the grade of steel to be annealed. This ratio must be closely controlled, or the atmosphere will become decarburizing or carburizing to the steel. Modern instruments, such as oxygen probes, are available to maintain this close control.

After carbon restoration, bars are cold drawn. Material processed in this manner is useful when parts must have full hardness on the cold-drawn (unmachined) surface after heat treatment. Many induction-hardened parts make use of a carbon-restored material as a means of eliminating machining.

Machinability

Cold drawing significantly improves the machinability of the steels discussed in this article. The increase in hardness due to cold work causes the chips formed by a cutting tool to tear away from the workpiece more readily, and to be harder and more brittle, so that they break up easily and are less likely to build up on the tool edge. Deformation extends a shorter distance above the edge of the tool, giving a sharper cleavage at that point. These factors contribute to improvements in power consumption, tool wear, and surface finish. They result from the addition of the major contributors to improvements in machinability: phosphorus, sulfur, nitrogen (diatomic), lead, bismuth, tellurium, selenium, calcium, and so on, in various combinations.

In addition, the accuracy of size and section of cold-finished bars minimizes collet troubles and requires less surface removal to obtain concentricity. The freedom from scale on the cold-finished bar also improves tool life and may permit the surface of the bar to be used as the finished surface of the completed part.

Cold drawing generally improves the machinability of low-carbon steels because the high ductility of these materials in the hot-rolled condition can be lowered considerably without raising strength excessively. In contrast, a steel such as 1144, which is inherently low in ductility because of its higher carbon content, shows little improvement in machining after cold drawing. The increased hardness that results from cold drawing can be deleterious to the machinability of the higher-carbon steels; it may be helpful to stress relieve after cold drawing to reduce hardness.

Another approach to maximum machinability with the higher-carbon grades is to anneal before cold drawing. This puts the carbide in a form that is less abrasive to the cutting tool. Lamellar anneal and spheroidize annealing are used depending on carbon level, machinability requirements, and heat treat response requirements. The trade-off values must be decided for each individual application. Compared with hot-rolled steel, uniformity of hardness and structure are improved.

One of the conventional indexes of machinability is the ratio of tool life to that encountered with 1212 cold-drawn bars. The average machinability ratings for cold-drawn carbon steel bars, nonresulfurized and resulfurized carbon steel bars, and alloy steel bars, based on a value of 100% for 1212 bars, are given in Tables 8, 9, 10, and 11. The relative machinability data listed in Tables 8, 9, 10, and 11 represent results obtained from experimental studies and actual shop production information on the general run of parts. Any extraordinary features of the part to be machined or physical conditions of the steel should be taken into consideration, and speeds and feeds altered accordingly. In addition, machinability is influenced by various metallurgical factors, such as degree of cold reduction, mechanical properties, grain size, and microstructure. Therefore, the data in Tables 8, 9, 10, and 11 are presented only as a starting point from which proper speeds and feeds for specific parts can be determined. Further discussion of the machinability of cold-drawn steel is included in the article "Machinability of Steels" in this Volume.

Table 8 Machinability ratings and recommended feeds and speeds for cold-drawn carbon steel bars

All cutting speeds and feeds based on cutting with high-speed steel tools. For cutting conditions for other machining operations, see the article "Machinability of Steels" in this Volume.

Steel designation AISI or SAE	Machinability rating ^(a) , %	Form turning			Single-point turning			Drilling		
		Width of cut, mm (in.)	Speed, m/min (sfm)	Feed, mm/rev (in./rev)	Depth of cut, mm (in.)	Speed, m/min (sfm)	Feed, mm/rev (in./rev)	Size of hole, mm (in.)	Speed, m/min (sfm)	Feed, mm/rev (in./rev)

- (a) Based on cutting with high-speed tool steels and a machinability rating of 100% for 1212 steel.
- (b) Type A is predominantly lamellar pearlite and ferrite. Type B is predominantly spheroidized. Type C is a hot-rolled structure that depends on grade, size, and rolling conditions of the producing mill. The structure may be coarse or fine pearlite or bainite. The pearlite at low magnification may be blocky or acicular. For descriptive information, see Ref 9. Type D is a structure resulting from a subcritical anneal or temper anneal. It is usually a granular or spheroidized carbide condition confined to the hot-rolled grain pattern, which may be blocky or acicular.

Machinability

Cold drawing significantly improves the machinability of the steels discussed in this article. The increase in hardness due to cold work causes the chips formed by a cutting tool to tear away from the workpiece more readily, and to be harder and more brittle, so that they break up easily and are less likely to build up on the tool edge. Deformation extends a shorter distance above the edge of the tool, giving a sharper cleavage at that point. These factors contribute to improvements in power consumption, tool wear, and surface finish. They result from the addition of the major contributors to improvements in machinability: phosphorus, sulfur, nitrogen (diatomic), lead, bismuth, tellurium, selenium, calcium, and so on, in various combinations.

In addition, the accuracy of size and section of cold-finished bars minimizes collet troubles and requires less surface removal to obtain concentricity. The freedom from scale on the cold-finished bar also improves tool life and may permit the surface of the bar to be used as the finished surface of the completed part.

Cold drawing generally improves the machinability of low-carbon steels because the high ductility of these materials in the hot-rolled condition can be lowered considerably without raising strength excessively. In contrast, a steel such as 1144, which is inherently low in ductility because of its higher carbon content, shows little improvement in machining after cold drawing. The increased hardness that results from cold drawing can be deleterious to the machinability of the higher-carbon steels; it may be helpful to stress relieve after cold drawing to reduce hardness.

Another approach to maximum machinability with the higher-carbon grades is to anneal before cold drawing. This puts the carbide in a form that is less abrasive to the cutting tool. Lamellar anneal and spheroidize annealing are used depending on carbon level, machinability requirements, and heat treat response requirements. The trade-off values must

be decided for each individual application. Compared with hot-rolled steel, uniformity of hardness and structure are improved.

One of the conventional indexes of machinability is the ratio of tool life to that encountered with 1212 cold-drawn bars. The average machinability ratings for cold-drawn carbon steel bars, nonresulfurized and resulfurized carbon steel bars, and alloy steel bars, based on a value of 100% for 1212 bars, are given in Tables 8, 9, 10, and 11. The relative machinability data listed in Tables 8, 9, 10, and 11 represent results obtained from experimental studies and actual shop production information on the general run of parts. Any extraordinary features of the part to be machined or physical conditions of the steel should be taken into consideration, and speeds and feeds altered accordingly. In addition, machinability is influenced by various metallurgical factors, such as degree of cold reduction, mechanical properties, grain size, and microstructure. Therefore, the data in Tables 8, 9, 10, and 11 are presented only as a starting point from which proper speeds and feeds for specific parts can be determined. Further discussion of the machinability of cold-drawn steel is included in the article "Machinability of Steels" in this Volume.

Table 8 Machinability ratings and recommended feeds and speeds for cold-drawn carbon steel bars

All cutting speeds and feeds based on cutting with high-speed steel tools. For cutting conditions for other machining operations, see the article "Machinability of Steels" in this Volume.

Steel designation AISI or SAE	Machinability rating ^(a) , %	Form turning			Single-point turning			Drilling		
		Width of cut, mm (in.)	Speed, m/min (sfm)	Feed, mm/rev (in./rev)	Depth of cut, mm (in.)	Speed, m/min (sfm)	Feed, mm/rev (in./rev)	Size of hole, mm (in.)	Speed, m/min (sfm)	Feed, mm/rev (in./rev)

Source: Ref 8

- (a) Based on cutting with high-speed tool steels and a machinability rating of 100% for 1212 steel.
- (b) Type A is predominantly lamellar pearlite and ferrite. Type B is predominantly spheroidized. Type C is a hot-rolled structure that depends on grade, size, and rolling conditions of the producing mill. The structure may be coarse or fine pearlite or bainite. The pearlite at low magnification may be blocky or acicular. For descriptive information, see Ref 9. Type D is a structure resulting from a subcritical anneal or temper anneal. It is usually a granular or spheroidized carbide condition confined to the hot-rolled grain pattern, which may be blocky or acicular.

Special Die Drawing

Two special die-drawing processes have been developed to give improved properties over those offered by standard drawing practices. These processes are cold drawing using heavier-than-normal drafts, followed by stress relieving; and drawing at elevated temperatures. In the production of steel bars by these special processes, drafts of approximately 10 to 35% reduction in cross-sectional area are employed at room or elevated temperature, depending on the practices and facilities of the individual producer. Stress-relieving temperatures vary over a similarly wide range, depending on producer facilities and end-product requirements. Typical tensile properties of plain carbon and alloy steel bars of medium carbon content subjected to special die-drawing processing are given in Table 12.

Table 12 Typical mechanical properties of special-die-drawn carbon and alloy steel bars of medium-carbon content

- (a) Typical minimum.
- (b) Typical hardness range, subject to negotiation. Hardness is taken on a flat below decarburization or on the midradius. In case of a disagreement between hardness and tensile or yield strength, the latter properties govern.
- (c) May contain lead or tellurium or other additives for improved machinability.

Heavy Drafts. Because of the engineering and economic advantages of cold-finished steels, a considerable effort has been made to improve the uniformity of mechanical properties after cold drawing. This has been accomplished by using heavier-than-normal drafts (10 to 35% reduction) followed by subcritical annealing. Stepwise or tandem drawing has been resorted to in order to avoid the formation of internal transverse fissures (cupping or bambooning) that may result from heavy drafts taken in one pass. The trend of property improvement resulting from this special practice can be seen in the comparison of normal and heavy drafts shown in Fig. 20.

Fig. 20 Effect of draft and stress-relieving temperature on the tensile properties of cold-drawn carbon steel bars. Solid curves are for bars given a normal draft; dashed curves are for bars given a heavy draft.

Heavier drafts produce higher tensile and yield strengths. Elongation can be substantially improved by stress relieving at 510 °C (950 °F), and this treatment still provides tensile and yield strengths higher than those obtainable with normal drafts. The combination of properties resulting from heavier drafts and higher stress-relieving temperatures is most desirable from the design standpoint. Such processing is most effective when applied to medium-carbon steels of either normal or higher manganese content. In the medium-manganese range, 1045 and 1050 respond most favorably; 1137, 1141, 1144, 1527, 1536, and 1541 show good response for the higher-manganese grades. The sulfur content of the 11xx steels improves machinability without lowering mechanical properties. Typical tensile properties for 1144 bars subjected to normal and heavy drafts are given in Table 13.

Table 13 Typical tensile properties of cold-drawn and stress-relieved 1144 grade (UNS G11440) carbon steel bars subjected to normal and heavy drafts

Steel bars that have been cold drawn using heavier-than-normal drafts and then stress relieved are often used in place of quenched and tempered bars, and as already noted, several resulfurized grades (1137, 1141, and 1144) respond readily to this process with resulting high strength values. Because the microstructures of these steels are still pearlitic, they machine more easily than their quenched and tempered counterparts. Therefore, although these grades cost more than nonresulfurized grades, they can provide significant savings in manufacturing costs, chiefly through the elimination of heat treating. However, even through the strength of the special cold-drawn and stress-relieved bars may be equal to that of quenched and tempered steel, it is not advisable to translate other properties from one condition to the other.

The torsional strength and endurance limits of these special-process bars are similar to those of quenched and tempered bars at the same strength level. The same is true for the wear resistance of bars of the same surface hardness. The impact

test values of the process bars, as measured by Izod or Charpy notched-bar test, are lower than those of quenched and tempered carbon steel bars and are significantly lower than those of quenched and tempered alloy steel bars. Failures of machine components usually result from fatigue, corrosion, wear, or shock loading. With the possible exception of the latter, there is no known correlation between instances of failure and the notched-bar impact test. When low temperatures or high pressures are involved and where there is doubt as to the suitability of these special-process bars, the design of the part should be reviewed.

Drawing at elevated temperatures between 95 and 540 °C (200 and 1000 °F), a special proprietary process, can, under optimum conditions, produce steel bars that have higher tensile and yield strengths than those of bars cold drawn with the same degree of reduction. The relative effects of cold drawing followed by stress relieving and of drawing at elevated temperature can be seen in Fig. 21. Both processes were carried out with 20% draft on 25 mm (1 in.) diam bars of 1144 steel. As shown in Fig. 21, elevated-temperature drawing affects tensile strength considerably, giving values somewhat greater than those for cold-drawn stress-relieved bars. For yield strength, the same general effects are evident, but the difference between the two processes is not as pronounced. The elongation values are quite similar for both processes.

Fig. 21 Effects of stress-relieving or drawing temperature on the (a) tensile strength and (b) yield strength of cold-drawn and stress-relieved bars and on hot drawn bars of 1144 steel. Bars, all from the same heat of steel and approximately 25 mm (1 in.) in diameter before drawing, were subjected to a draft of about 20%. Source: Ref 11

Figures 22, 23, 24, and 25 show the effects of two drafts and increasing drawing temperatures on bars of each of four steels. Between 260 and 315 °C (500 and 600 °F), tensile and yield strengths reach maximums and elongation and reduction in area reach minimums. Strength for any given drawing temperature increases with increased draft, with minor exceptions. Depending on chemical composition, a certain minimum draft is required to fully develop the effect on strength properties of drawing at elevated temperature. In general, the draft taken at room temperature would have to be doubled in order to match the strength developed in drawing at elevated temperature. The yield strengths of all four steels were increased from 12 to 35%, depending on percentage reduction in drawing and on drawing temperature. Carbon steels were less affected by increased draft than alloy steel 4140 when drawn at elevated temperatures.

Fig. 22 Effects of drawing temperature and percentage reduction on mechanical properties of 19 mm ($\frac{3}{4}$ in.) diam cold-drawn 1018 steel bars. Source: Ref 12

Fig. 23 Effects of drawing temperature and percentage reduction on mechanical properties of 14 mm ($\frac{9}{16}$ in.) diam cold-drawn 1080 steel bars. Source: Ref 12

Fig. 24 Effects of drawing temperature and percentage reduction on mechanical properties of 16 mm ($\frac{5}{8}$ in.) diam cold-drawn 1144 steel bars. Source: Ref 12

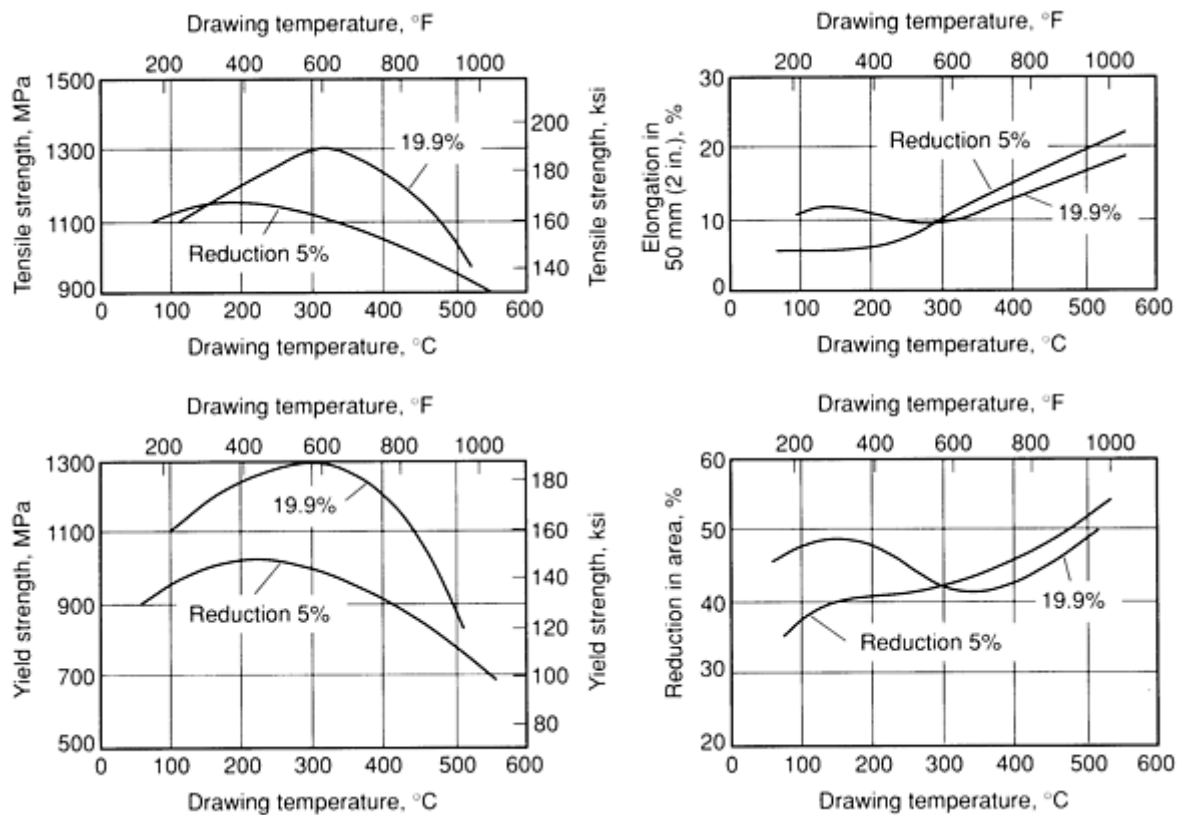

Fig. 25 Effects of drawing temperature and percentage reduction on mechanical properties of 16 mm ($\frac{5}{8}$ in.)

diam cold-drawn 4140 steel bars. Source: Ref 12

The pronounced effect of drawing at elevated temperatures changes the shape of the stress-strain curve from round to sharp-kneed, as shown in Fig. 26. Hot drawing reverses the effect of cold work, that is, automatically stress relieves the steel. This effect on the stress-strain curve is significant in applications in which minimum plastic deformation is permissible, such as a stud that requires a proof load high in relation to its tensile strength.

Fig. 26 Effect of drawing temperature on the shape of the tensile stress-strain curve for hot-drawn 1144 steel bars. Bars were reduced 7.2% to a diameter of 21.4 mm ($\frac{27}{32}$ in.). Source: Ref 12

Typical yield strength minimums for 1144 bars before and after drawing are as follows:

	MPa	ksi
As-hot-rolled	345	50
Cold drawn (normal draft) and stress relieved at low temperature	550	80
Cold drawn (heavy draft) and stress relieved at high temperature	690	100
Drawn at elevated temperature	860	125

The effect of drawing temperature on notched-bar impact values is shown in Fig. 27. Although impact values decrease with the first increase in drawing temperature, they later rise significantly. Thus, it may be possible to select a drawing temperature that will provide both good static strength and satisfactory notched-bar impact strength.

Fig. 27 Effect of drawing temperature on the impact properties of hot-drawn bars of two steels. Source: Ref 12

Introduction

WIRE ROD is a semifinished product rolled from billet on a rod mill and is used primarily for the manufacture of wire. The steel for wire rod is produced by all the modern processes, including the basic oxygen, basic open hearth, and electric furnace processes. Steel wire rod is usually cold drawn into wire suitable for further drawing; for cold rolling, cold heading, cold upsetting, cold extrusion, or cold forging; or for hot forging.

Although wire rod may be produced in several regular shapes, most is round in cross section. Round rod is usually produced in nominal diameters of 5.6 to 18.7 mm ($\frac{7}{32}$ to $\frac{47}{64}$ in.), advancing in increments of 0.4 mm ($\frac{1}{64}$ in.).* As the rod comes off the rolling mill, it is formed into coils. These coils are usually about 760 mm (30 in.) in inside diameter and weigh up to 2000 Kg (4400 lb). The dimensions and maximum weight of a single coil are determined by the capabilities of the rolling mill. Coil weights that exceed the capabilities of the rolling mill sometimes can be obtained by welding two or more coils together. The standard tolerances are ± 0.4 mm ($\pm \frac{1}{64}$ in.) on the diameter and 0.64 mm (0.025 in.) maximum out-of-roundness.

Producers of wire rod may market their product as rolled, as cleaned and coated, or as heat treated, although users generally prefer to do such preparations themselves. These operations are explained in the following sections, along with the several recognized quality and commodity classifications applicable to steel wire rods.

Acknowledgements

The helpful suggestions provided by Zeev Zimmerman, Bethlehem Steel Corporation, and Bhaskar Yalamanchili, North Star Steel Texas Company, are greatly appreciated.

Note

* Because steel wire rod manufactured in the United States is customarily produced to fractional-inch sizes, rather than decimal-inch or millimeter sizes, the millimeter conversion for wire rod sizes may not be a multiple of the 0.4 mm ($\frac{1}{64}$ in.) increment size.

Cleaning and Coating

Mill scale is cleaned from steel wire rods by pickling or caustic cleaning followed by water rinsing, or by mechanical means such as shot blasting with abrasive particles or reverse bending over sheaves. The chemical cleaning of steel wire rods is always followed by a supplementary coating operation. Lime, borax, or phosphate coating is applied to provide a carrier for the lubricant necessary for subsequent processing into wire. In lime coating, practices may be varied in order to apply differing amounts of lime on the rods depending on the customer requirements. Phosphate-coated rods may have a supplementary coating of lime, borax, or water-soluble soap. Mechanically descaled rods may be drawn without coating using only wire drawing soaps, or may be coated in a fashion similar to that used for chemically cleaned rods.

Heat Treatment

The heat treatments commonly applied to steel wire rod, either before or during processing into wire, include annealing, spheroidize annealing, patenting, and controlled cooling. Annealing commonly involves heating to a temperature near or below the lower critical temperature and holding at that temperature for a sufficient period of time, followed by slow cooling. This process softens the steel for further processing, but not to the same degree as does spheroidize annealing. Spheroidize annealing involves prolonged heating at a temperature near or slightly below the lower critical temperature (or thermal cycling at about the lower critical temperature), followed by slow cooling, with the object of changing the shape of carbides in the microstructure to globular (spheroidal), which produces maximum softness.

Patenting is a heat treatment usually confined to medium-high-carbon and high-carbon steels. In this process, individual strands of rod or wire are heated well above the upper critical temperature and then are cooled comparatively rapidly in air, molten salt, molten lead, or a fluidized bed. The object of patenting is to develop a microstructure of homogeneous, fine pearlite. This treatment generally is employed to prepare the material for subsequent wire drawing.

Controlled cooling is a heat treatment performed in modern rod mills in which the rate of cooling after hot rolling is carefully controlled. The process imparts uniformity of properties and some degree of control over scale, grain size, and microstructure.

Carbon Steel Rod

Carbon steels are those steels for which no minimum content is specified or required for chromium, nickel, molybdenum, tungsten, vanadium, cobalt, niobium, titanium, zirconium, aluminum, or any other element added to obtain a desired alloying effect; for which specified minimum copper content does not exceed 0.40%; for which specified maximum manganese content does not exceed 1.65%; and for which specified maximum silicon or copper content does not exceed 0.60%. In all carbon steels, small quantities of certain residual elements, such as chromium, nickel, molybdenum, and copper, are unavoidably retained from raw materials. These elements are considered incidental, although maximum limits are commonly specified for specific end-uses.

Carbon steel rods are produced in various grades, or compositions:

- Low-carbon steel wire rods (maximum carbon content $\leq 0.15\%$)
- Medium-low-carbon steel wire rods (maximum carbon content $> 0.15\%$, but $\leq 0.23\%$)
- Medium-high-carbon steel wire rods (maximum carbon content $> 0.23\%$, but $\leq 0.44\%$)
- High-carbon steel wire rods (maximum carbon content $> 0.44\%$)

Ordinarily, sulfur and phosphorus contents are kept within the usual limits for each grade of steel, while carbon, manganese, and silicon contents are varied according to the mechanical properties desired. Occasionally, sulfur and/or phosphorus may be added to the steel to improve the machinability.

Qualities and Commodities of Carbon Steel Rod

Rod for the manufacture of carbon steel wire is produced with manufacturing controls and inspection procedures intended to ensure the degree of soundness and freedom from injurious surface imperfections necessary for specific applications. The various quality descriptors and commodities applicable to carbon steel wire rod are described below.

Industrial quality rod is manufactured from low-carbon or medium-low-carbon steel and is intended primarily for drawing into industrial quality wire. Rod of this quality is available in the as-rolled or heat-treated conditions. Practical limitations for drawing are: low-carbon rod 5.6 mm ($\frac{7}{32}$ in.) in diameter can be drawn without intermediate annealing to

2.0 mm (0.080 in.) by five conventional drafts; medium-low-carbon rod 5.6 mm ($\frac{7}{32}$ in.) in diameter can be drawn without intermediate annealing to 2.69 mm (0.106 in.) by four conventional drafts.

Chain Quality Rod. Rod for the manufacture of wire to be used for resistance welded chain is made from low-carbon and medium-low-carbon steel produced by practices that ensure their suitability for drawing into wire for this end-use. Good butt welding uniformity characteristics and internal soundness are essential for this application. Rod for the manufacture of wire to be used for fusion welded chain can be produced from specially selected low-carbon rimmed steel, but is more often made from continuous cast steel.

Fine wire quality rod is suitable for drawing into small-diameter wire either without intermediate annealing treatments or with only one such treatment. Rod 5.6 mm ($\frac{7}{32}$ in.) in diameter can be direct drawn into wire as fine as 0.9 mm (0.035 in.) without intermediate annealing. Wire finer than 0.9 mm (0.035 in.), for such products as insect-screen

wire, weaving wire, and florist wire, is usually drawn in two steps: reducing to an intermediate size no smaller than 0.9 mm (0.035 in.), followed by annealing and redrawing to final size.

Fine wire quality rod is generally rolled from steel of grade 1005 or 1006 produced using techniques to provide good surface finish and internal cleanliness. In addition to these precautions, the producer may subject the rod to tests such as fracture or macroetch tests.

Cold finishing quality rod is intended for drawing into cold finished bars; the manufacture of such rod is controlled to ensure suitable surface conditions.

Heading, Cold Extrusion, or Cold Rolling Quality Rod. Rod used for the manufacture of heading, forging, cold extrusion or cold rolling quality wire is produced by closely controlled manufacturing practices. It is subject to mill testing and inspection to ensure internal soundness and freedom from injurious surface imperfections. Heat treatment as a part of wire mill processing is very important in the higher carbon grades of steel. For common upsetting, represented by the production of standard trimmed hexagon-head cap screws, 1016 to 1038 steel wire drawn from annealed rod is suitable. Wire for moderate upsetting, also produced from 1016 to 1038 steel, should be drawn from spheroidize annealed rod or should be in-process annealed. Wire for severe heading and forging, produced from rod of 1016 to 1541 steel, should be spheroidize annealed in process or at finished size. Rod of this quality is not intended for recessed-head or similar special-head applications.

In the production of rod for heading, forging, or cold extrusion is killed carbon steels with nominal carbon contents of 0.16% or more (AISI grades 1016 or higher), both austenitic grain size and decarburization should be controlled. Such steels can be produced with either fine or coarse austenitic grains, depending on the type of heat treatment and end-use. The maximum allowable amounts of decarburization as defined by the average value for the depth of the layer of free ferrite plus the layer of partial decarburization (the total affected depth) and the average depth of the layer of free ferrite alone are given below:

Nominal rod diameter, mm (in.)	Average depth of decarburization			
	Free ferrite		Total affected	
	mm	in.	mm	in.
$\leq 9.6 (\leq \frac{3}{8})$	0.10	0.004	0.30	0.012
10-12.8 ($\frac{25}{64} - \frac{1}{2}$)	0.13	0.005	0.36	0.014

If decarburization limits closer than these standard limits are required in a given manufactured product, it is sometimes necessary to incorporate means for carbon restoration in the annealing process. When there are discrepancies in decarburization test results, it is customary to make heat-treatment tests of the finished product to determine suitability for the particular application.

Wood screw quality rod includes low-carbon resulfurized and nonresulfurized wire rod for drawing into wire for the manufacture of slotted-head screws only, not for recessed-head or other special-head screws.

Scrapless Nut Quality Rod. Rod to be drawn into wire for scrapless nuts is produced by specially controlled manufacturing practices. It is subjected to mill tests and inspection designed to ensure internal soundness; freedom from injurious segregation and injurious surface imperfections; and satisfactory performance during cold heading, cold expanding, cold punching, and thread tapping.

Rod for scrapless nut wire commonly is made from low-carbon, resulfurized steels. Nonresulfurized steels are also used; these steels ordinarily are furnished only in grades containing more carbon than the resulfurized grades and with phosphorus content not exceeding 0.035% and sulfur content not exceeding 0.045% by heat analysis.

In making resulfurized steel for scrapless nut quality rod, either an ingot or continuous casting process can be used. In an ingot manufacturing process, sometimes the sulfur content is obtained through delayed mold additions to a conventional nonresulfurized rimming steel. The purpose of such a practice is to produce a steel consisting of a rim of low-sulfur steel suitable for expansion during nut forming around a high-sulfur interior section suitable for the piercing and threading operations involved in making scrapless nuts. When high sulfur content is secured through such mold additions, sulfur analyses are made on the solid billets rather than by heat analysis. It is customary to produce these steels to a specified sulfur range of either 0.08 to 0.13% or 0.04 to 0.09%. Because of the practice used in making the steel and the degree to which sulfur segregates, the sulfur content at various locations in a billet may vary from the indicated range.

When a continuous casting process is used to make resulfurized steel, the sulfur content is typically more uniform than the ingot process. However, continuous casting precludes the rimming practice described in the above paragraph.

Severe cold heading, severe cold extrusion, or severe scrapless nut quality rod is used for severe single-step or multiple-step cold forming where intermediate heat treatment and inspection are not possible. Rod of this quality is produced with carefully controlled manufacturing practices and rigid inspection practices to ensure the required degree of internal soundness and freedom from surface imperfections. A fully killed fine-grain steel is usually required for the most difficult operations. Normally, the wire made from this quality rod is spheroidize annealed, either in process or after drawing finished sizes. Decarburization limits and the steels to which they apply are the same as those described in the section "Heading, Cold Extrusion, or Cold Rolling Quality Rod" in this article.

Welding-quality rod is used to make wire for gas or electric-arc welding filler metal. Welding-quality rod can be made from selected ingots or billets of low-carbon rimmed, capped, or killed steel, but is preferably made from continuous cast steel. It is produced to several restricted ranges and limits to chemical composition; an example of the restricted ranges and limits for low-carbon, arc welding wire rod is shown below:

Element	Heat analysis, %
Carbon	0.10-0.15
Manganese	0.40-0.60
Phosphorus	0.025 max
Sulfur	0.035 max
Silicon	0.030 max

Rod for welding-quality wire constitutes an exception to the general practice that rimmed or capped steel is not commonly subject to product analysis. Experience to date has shown the necessity for close control of composition, and therefore only billets from those portions of the ingot that conform to the applicable ranges and limits are used for welding-quality rod. For the majority of welding-quality rod that is made from continuous cast steel, these product checks may not be necessary.

Medium-high-carbon and high-carbon quality rod is wire rod intended for drawing into such products as strand wire, lockwasher wire, tire bead wire, upholstery spring wire, rope wire, screen wire (for heavy aggregate screens), aluminum cable steel reinforced core wire, and prestressed concrete wire.

These wire qualities are normally drawn directly from patented or control-cooled rod. When drawing to sizes finer than 2.0 mm (0.080 in.) (from 5.6 mm, or $\frac{7}{32}$ in., rod), it is customary to employ in-process heat treatment before drawing to finish size. Medium-high-carbon and high-carbon quality rod is not intended for the manufacture of higher-quality wires such as music wire or valve spring wire.

Rod for Special Purposes. In addition to the carbon steel rod commodities described above, which have specific quality descriptors, several other commodities are produced, each having the characteristics necessary for a specific application, but for which no specific quality descriptor exists. Some of these commodities are made to standard specifications; the others are made to proprietary specifications that are mutually acceptable to both producer and user.

Rod for music wire, valve spring wire, and tire cord wire is rolled and conditioned to ensure the lowest possible incidence of imperfections. Surface imperfections are objectionable because they lower the fatigue resistance that is important in many of the end products made from these wires. Internal imperfections are objectionable because they make the rod unsuitable for cold drawing to high strength levels and the extremely fine sizes required.

Rod for concrete reinforcement is nondeformed rod produced from steel chemical compositions selected to provide the mechanical property requirements for grade 40 and grade 60, as described in ASTM A 615. This quality rod is produced in coils.

Rod for telephone and telegraph wire is produced by practices and to chemical compositions intended for the manufacture of wire having electrical and mechanical properties that will meet the requirements of the various grades of this type of wire.

Special Requirements for Carbon Steel Rod

Some of the quality descriptors discussed above imply special requirements for the manufacture and testing of wire rod. A few of the more common requirements are listed below. For some applications, it may be appropriate to add one or more special requirements to those implied by the quality descriptor.

Macroetch testing is deep-etch testing to evaluate internal soundness. A representative cross section is etched in a hot acid solution.

Fracture Testing. In fracture testing, a specimen is fractured to evaluate soundness and homogeneity.

Austenitic Grain Size Requirements. For applications involving carburizing or heat treatment, austenitic grain size for killed steels may be specified as either coarse (grain size 1 through 5) or fine (grain size 5 through 8 inclusive), in accordance with ASTM E 112.

Heat-Treating Requirements. When heat-treating requirements must be met in the purchaser's end product, all heat treatment procedures and mechanical property requirements should be clearly specified.

Nonmetallic inclusion testing comprises a microscopic examination of longitudinal sections of the rod to determine the nature and frequency of nonmetallic inclusions. Methods B or C of ASTM E 45 are commonly used.

Decarburization limits are specified for special applications when required. A specimen is polished so that the entire cross-sectional area is in a single plane, with no rounded edges. After etching with a suitable etchant, the specimen is

examined microscopically (usually to 100 diameters), and the results are reported in hundredths of a millimeter or thousandths of an inch. The examination includes the entire periphery, and the results reported should include the amount of free ferrite and the total depth of decarburization. Further details of this microscopic method are contained in SAE Recommended Practice J419,

Mechanical Properties of Carbon Steel Rod

In the older mills, where rod was coiled hot, there was considerable variation within each coil because of the effect of varying cooling rates from the center to the periphery of the coil. Therefore, as-hot-rolled rod was seldom sold to specific mechanical properties because of the inherent variations of such properties. These properties for a given grade of steel varied from mill to mill and were influenced by both the type of mill and the source of steel being rolled.

In new rod mills, which are equipped with controlled cooling facilities, this intracoil variation is kept to a minimum. In such mills, finishing temperature, cooling of water, cooling air, and conveyor speed all are balanced to produce rod with the desired scale and microstructure. This structure, in turn, is reflected in the mechanical properties of the rod and permits the rod to be drawn directly for all but the most demanding applications. The primary source of intracoil variation on these new mills is the overlapping of the coiled rings on the conveyor. These overlapped areas cool at a slower rate than the majority of the ring.

Table 1 lists typical values of tensile strength for 5.6 mm ($\frac{7}{32}$ in.) low-carbon steel rod rolled on a modern rod mill equipped with controlled cooling facilities. The values shown are for rods rolled with full air cooling. Tensile strength values for larger-diameter rod are lower, decreasing by approximately 1.9 MPa (270 psi) for each 0.4 mm ($\frac{1}{64}$ in.) increment by which rod diameter exceeds 5.6 mm ($\frac{7}{32}$ in.). Similar analyses of rods rolled without full air cooling or rods rolled on an older mill, where the steel is coiled hot, would be expected to reveal lower tensile strength.

Table 1 Tensile strength of 5.6 mm ($\frac{7}{32}$ in.) diam hot-rolled low-carbon steel rod

Data obtained from rod produced with controlled cooling

Steel grade	Rimmed		Capped		Aluminum killed fine-grain steel		Silicon killed fine- or coarse-grain steel	
	MPa	ksi	MPa	ksi	MPa	ksi	MPa	ksi
1005	350	51	380	55	395	57
1006	360	52	365	53	395	57	405	59
1008	370	54	385	56	405	59	425	62
1010	385	56	400	58	420	61	440	64
1012	405	59	420	61	435	63	455	66
1015	425	62	440	64	450	65	475	69
1017	450	65	455	66	455	66	495	72

1018	475	69	490	71	525	76
1020	470	68	475	69	485	70	510	74
1022	520	75	565	82

Table 2 shows typical expected tensile strength values for 5.6mm ($\frac{7}{32}$ in.) medium-high-carbon and high-carbon steel rods rolled on a mill utilizing controlled cooling. The microstructure of such rod approximates that obtained by patenting. The strength generally falls between those obtained by air patenting and lead patenting. Most high-carbon steel wire is drawn from such rods without prior patenting. Tensile strengths for large-diameter rods have been found to average 5.2 MPa (750 psi) lower for each 0.4 mm ($\frac{1}{64}$ in.) increment in diameter over 5.6 mm ($\frac{7}{32}$ in.). Additional strength in control-cooled high-carbon rods can be achieved by using microalloying techniques. These procedures should be used with caution because they may affect other properties such as ductility and durability.

Table 2 Tensile strength of 5.6 mm ($\frac{7}{32}$ in.) diam hot-rolled medium-high-carbon and high-carbon steel rod

Data obtained from rod produced with controlled cooling

Alloy Steel Rod

Alloy steels are those steels for which maximum specified manganese content exceeds 1.65% or maximum specified silicon or copper content exceeds 0.60%; or for which a definite range or definite minimum quantity of any other element is specified in order to obtain desired effects on properties. Detailed information on composition ranges and limits of alloy steels can be found in the article "Classification and Designation of Carbon and Low-Alloy Steels" in this Volume.

Qualities and Commodities for Alloy Steel Rod

The various qualities of alloy steel wire rod possess characteristics that are adapted to the particular conditions typically encountered during fabrication or service. Manufacture of these steels normally includes careful selection of raw materials for melting, exacting steelmaking practices, selective discard (when the steel is produced in ingots), extensive billet preparation, and extensive testing and inspection.

Occasionally, alloy steel of a special quality is specified for the manufacture of wire rod. Aircraft quality alloy steel may be specified for wire rods intended for processing into critical or highly stressed aircraft parts or for similar purposes. Bearing quality alloy steel may be specified for wire rods intended for processing into balls and rollers for antifriction bearings. Bearing quality alloy steel is usually specified when purchasing the standard carburizing grades, such as 4118, 4320, 4620, 4720, and 8620, or the through-hardening, high-carbon chromium grades such as E51100 and E52100. The various standard qualities and commodities available in alloy steel wire rod are described below.

Cold heading quality alloy steel rod is used for the manufacture of wire for applications involving cold plastic deformation by such operations as upsetting, heading, forging, or extrusion. Typical parts are fasteners (cap screws, bolts, eyebolts), studs, anchor pins, and balls and rollers for antifriction bearings.

Special cold heading quality alloy steel rod is used for wire for applications involving severe cold plastic deformation. Surface quality requirements are more critical than for cold heading quality. Steel with very uniform chemical composition and internal soundness, as well as special surface preparation of the semifinished steel, are required. Typical applications are ball joint suspension studs, socket head screws, recessed-head screws, and valves.

Welding quality alloy steel rod is used for the manufacture of wire used as filler metal in electric arc welding or for building up hard wearing surfaces of parts subjected to wear. The heat analysis limits give below for phosphorus and sulfur apply to this quality rod:

Steelmaking process	Maximum percent	
	P	S
Basic electric	0.025	0.025

Special Requirements for Alloy Steel Rod

Alloy steel rod can be produced with special requirements in addition to those implied by the quality descriptors discussed above. These special requirements include those given below.

Special surface entails a product with minimal frequency and severity of seams and other surface imperfections.

Decarburization limits can be specified for special applications. An example of such limits are those shown in the table below for alloy steel rod for wire for heading, forging, roll threading, extrusion, lockwasher, and screwdriver applications. Listed below are the maximum allowable amounts of decarburization as defined by the average value for the depth of the layer of free ferrite plus the layer of partial decarburization (the total affected depth) and the average depth of the layer of free ferrite alone:

Nominal rod diameter, mm (in.)	Average depth of decarburization			
	Free ferrite		Total affected	
	mm	in.	mm	in.
$\leq 6.4 (\leq \frac{1}{4})$	0.08	0.003	0.20	0.008
$6.8-9.6 (\frac{17}{64}-\frac{3}{8})$	0.08	0.003	0.25	0.010
$10-12.8 (\frac{25}{64}-\frac{1}{2})$	0.10	0.004	0.30	0.012
$13-18 (\frac{33}{64}-\frac{45}{64})$	0.13	0.005	0.36	0.014

Source: SAE J413

When limits closer than those given above are required for the end product, it is sometimes appropriate to incorporate carbon restoration in the fabrication process. For some applications, the rod producer can include carbon restoration in the mill heat treatment. The method of measuring decarburization is the same as that described for carbon steel rods.

Heat-Treating Requirements. When the end product must be heat treated, the heat treatment and mechanical properties should be clearly defined.

Hardenability requirements are customarily specified by H-steel designations and hardenability bands. These steels and hardenability bands are discussed in the article "Hardenability of Carbon and Low-Alloy Steels" in this Volume.

Austenitic Grain Size Determination. Most alloy steels are produced using fine-grain practice. Fine-grain steels are useful in carburized parts, especially when direct quenching is involved, and are less sensitive than coarse-grain steels to variations in heat-treating practices. Coarse-grain steels are deeper hardening and are generally considered more machinable. Austenitic grain size is specified as either coarse (grain sizes 1 through 5) or fine (grain sizes 5 through 8), determined in accordance with ASTM E 112.

Nonmetallic-Inclusion Testing. When the nonmetallic-inclusion test is specified, it is commonly done on billets. Prepared and polished specimens are examined microscopically at 100 diameters. Sample locations, number of tests, and limits of acceptability should be established in each instance. Test procedures are described in ASTM E 45.

Magnetic-Particle Inspection. For alloy steel rod and wire products subject to magnetic-particle inspection, it is customary for the producer to test the product in a semi-finished form, such as billets (using specimens properly machined from billets), to ensure that the heat conforms to the magnetic-particle inspection requirements, prior to further processing.

The method of inspection consists of suitably magnetizing the steel and applying a prepared magnetic powder, either dry or suspended in a suitable liquid, that adheres to the steel along lines of flux leakage. On properly magnetized steel, flux leakage develops along surface or subsurface discontinuities. The results of the inspection will vary with the degree of magnetization, the inspection procedure (including such conditions as relative location of surfaces tested), the method and sequence of magnetizing and applying the powder, and the interpretation. The testing procedure and standards of acceptance for magnetic-particle inspection are described in Aerospace Materials Specification 2301.

Macroetch Testing. Soundness and homogeneity of alloy steel rod are sometimes evaluated macroscopically by examining a properly prepared cross section of the product after it has been immersed in a hot acid solution. It is customary to use hydrochloric acid for this purpose.

Steel Wire

Revised by Allan B. Dove, Consultant

Introduction

WIRE can be cold drawn from any of the types of carbon steel or alloy steel rod described in the article "Steel Wire Rod" in this Volume. For convenience, the various grades of carbon steel wire can be divided into the same four classes used for carbon steel rod. Based on carbon content, these classes are:

- Low-carbon steel wire (0.15% C max)
- Medium-low-carbon steel wire (>0.15 to 0.23% C)
- Medium-high-carbon steel wire (>0.23 to 0.44% C)
- High-carbon steel wire (>0.44% C)

The conventional four-digit or five-digit American Iron and Steel Institute--Society of Automotive Engineers (AISI-SAE) designation is used to specify the carbon or alloy steel used to make the wire. Carbon and alloy steel wire can be produced in qualities suitable for cold rolling, cold drawing, cold heading, cold upsetting, cold extrusion, cold forging, hot forging, cold coiling, heat treatment, or carburizing and for a wide variety of fabricated products.

Acknowledgements

The contributions of the following individuals were critical in the preparation of this article. T.A. Heuss, LTV Steel Bar Division; Bill Schuld, Seneca Wire and Manufacturing Company; and Walter Facer, American Spring Wire Company.

Wire Configurations and Sizes

Shapes of Wires. Although wire is ordinarily thought of as being only round, it may have any one of an infinite number of sectional shapes, as required by end use. After ordinary round wire, the most common shapes are square, hexagonal, octagonal, oval, half-oval, half-round, triangular, keystone, and flat. In addition to these regular (symmetrical) shapes, wire is also made in various odd and irregular shapes for specific purposes.

Flat wire, as defined by AISI, is wire that has been cold rolled or drawn, has a prepared edge, is rectangular in shape, 25 mm (1 in.) or less in width, and less than 9.5 mm ($\frac{3}{8}$ in.) in thickness. Flat wire is generally produced from hot-rolled rods or specially prepared round wire by one or more cold-rolling operations intended primarily for the purpose of obtaining the size and section desired and for improving surface finish, dimensional accuracy, and mechanical properties.

Low-carbon steel flat wire can also be produced by slitting cold-rolled flat sheet or strip steel to the desired width. The width-to-thickness ratio and the specified type of edge generally determine the process that will be necessary to produce a specific flat wire item. The edges, finishes, and tempers obtainable in flat wire are similar to those furnished in cold-rolled strip. It should be noted that a product having an approximately rectangular section, rolled from carbon steel round wire of selected size, without edge, is also known as carbon steel flat wire.

Sizes of Wire. The size limits for the product commonly known as wire range from approximately 0.13 mm (0.005 in.) to (but not including) 25.4 mm (1 in.) for round sections and from a few tenths of a millimeter to approximately 16 mm ($\frac{5}{8}$ in.) for square sections. Larger rounds and squares (if passed through a die or rolled) and all sizes of hexagonal and octagonal sections are commonly known as cold-drawn bars.

The size (diameter) of round wire is expressed in decimal units or by gage numbers. In the United States, the conventional unit is the inch, and wire diameter is determined with micrometers capable of making measurements accurate to at least one thousandth of an inch. Sizes specified are expressed in ten thousandths of an inch, which should be followed by the metric dimension in brackets to two decimal places. There are several different systems of gage numbers that can be used for the measurement of wire, but in general these systems have fallen into disuse and have been replaced by sizes in thousandths of an inch or by metric dimensions. The size of music wire is usually expressed in music wire gage (MWG), which is the standard for this wire application. For iron and steel telephone and telegraph wire, the standard is the Birmingham wire gage (BWG) system. The system commonly used by manufacturers of steel wire (other than the exceptions noted) is the United States steel wire gage (USSWG) or, more commonly, the steel wire gage (SWG) system, and all unidentified gage numbers used in this article will refer to this system. The use of gage numbers for steel wire measurements is falling from favor, and the use of absolute units is gaining acceptance. Table 1 lists decimal equivalents in inches and millimeters for steel wire gage numbers from 7/0 (12.45 mm, or 0.490 in.) to 50 (0.112 mm, or 0.0044 in.).

Wire 20 gage and smaller in size is usually regarded as fine; wire of these sizes is normally drawn and coiled on 203 mm (8 in.) diam blocks. Larger blocks are used as finished wire diameter increases. For example, 2.34 or 0.092 in. (13 gage) wire is generally drawn on 559 mm (22 in.) blocks. Table 2 indicates the usual block sizes by gages for wires between 0.889 and 12.70 mm (0.035 and 0.500 in.).

Table 2 Wiredrawing block sizes and corresponding coil diameters for coarse round wire

(a) Nearest actual metric block size commonly manufactured.

(b) Metric sizes shown were rounded off to the nearest 25 mm. The figures on inside coil diameter are for guidance only. The inside diameter of the coil of wire after stripping from the block varies depending on the coil weight, grade of steel, type of riding stripper used, and size of wire. Generally, the inside diameter is slightly less than block diameter. The coils of the larger-size wire and higher-chemistry grades may have a tendency to expand.

Wire in gages 17 to 19 may be regarded as either fine or coarse, depending on manufacturing process and end use. The most commonly used wires are 8 to 20 gages in size and may be drawn from 5.6 mm ($\frac{7}{32}$ in.) diam rod. Tables 3(a), 3(b), 4(a), 4(b), 4(c) list some standard size tolerances for coarse and fine carbon steel round wire.

Table 3(a) Size tolerances of galvanized coarse round wire available in coils

Wire diameter		Tolerances ^(a)					
		Regular or Type 1 coating		Type 2 coating		Type 3 coating	
mm	in.	mm	in.	mm	in.	mm	in.
0.889 to <1.93	0.035 to <0.076	±0.05	±0.002	±0.05	±0.002	±0.05	± 0.002
1.93 to <3.76	0.076 to <0.148	±0.08	±0.003	±0.08	±0.003	±0.10	± 0.004
3.76 to 6.35	0.148 to 0.250	±0.08	±0.003	±0.08	±0.003	±0.10	± 0.004
> 6.35	> 0.250	± 0.08	± 0.003	± 0.10	± 0.004	± 0.13	± 0.005

- (a) It is recognized that the surface of heavy zinc coating, particularly those produced by hot galvanizing, are not perfectly smooth and devoid of irregularities. If the tolerances shown above are rigidly applied to such irregularities that are inherent in the product, unjustified rejections of wire that would actually be satisfactory for use could occur. Therefore, it is intended that these tolerances be used in gaging the uniform areas of the galvanized wire. For certain galvanized wire commodities, different size tolerances are applicable, as shown under the specific commodity descriptions.

Table 3(b) Size tolerances of uncoated coarse round wire available in coils

Wire diameter		Diameter tolerance		Out-of-round tolerance	
mm	in.	mm	in.	mm	in.
0.889 to <1.93	0.035 to <0.076	±0.03	±0.001	±0.03	± 0.001
1.93 to <12.70	0.076 to <0.500	±0.05	±0.002	±0.05	± 0.002
12.70 to ≤25.37	0.500 to ≤0.999	± 0.08	± 0.003	± 0.08	± 0.003

Table 4(a) Size tolerances for galvanized fine round wire available in coils

These tolerances are applicable to fine wire that is coated by conventional galvanizing procedures without the introduction of a prior annealing operation and are not appropriate for wire that is annealed by a separate operation following cold drawing and before the galvanizing operation.

Wire diameter		Tolerance ^(a)

(a) Tolerances shown are generally followed by the producers

Wiremaking Practices

Wiredrawing. Steel wire is produced from coils of wire rod, after removal of scale, by one or more cold reduction processes intended primarily for the purpose of obtaining the desired size. Wiredrawing, which improves surface finish and dimensional accuracy, is the most common cold reduction process. A natural result of cold drawing is that the resultant wire develops mechanical and physical properties different from those of hot-rolled steel of like composition. By varying the amount of cold reduction and other wire mill practices, including thermal treatment, a wide variety of properties and finishes can be obtained.

The mechanical characteristics of steel wire (tensile strength, stiffness, ductility, hardness, and so on) result from wire mill treatment as well as from chemical composition; therefore, the mechanical properties of wire are less dependent on chemical composition than those of other steel mill forms. In most cases, the purchaser of wire is interested in suitable mechanical properties for a given application rather than in chemical composition.

Prior to drawing, the scale is removed from the material by acid pickling or mechanical descaling. If chemically cleaned, the coil is then rinsed with water, dipped in a vat containing lime in suspension or other material in solution, and in some cases baked to dry the coating and to liberate the mobile hydrogen that may have been absorbed by the steel during pickling.

In the cold drawing of wire, coiled rod or bar is drawn through the tapered hole of a die or through a series of dies; the number of dies used depends on the finished diameter required. In the past, the smallest rod section used was 5.6 mm ($\frac{7}{32}$ in.), but a few rod producers now provide 4 mm (0.157 in.) material. To begin drawing, one end of the rod is swaged to a point, inserted through the die, and attached to a power-driven reel (block). The block then pulls the material through the die and coils the drawn wire.

The common design of a wiredrawing die (Fig. 1) consists of a supporting ring of steel encasing a hard, wear-resistant nib. The nib consists of one or more carbides (such as tungsten, tantalum, or titanium) mixed with a bonding agent (such as cobalt), pressed into the desired shape, and sintered into its hardened rough form, after which it is mounted, sized, and polished. Diamond dies are sometimes used instead of carbide dies for special fine wire applications. The finest sizes, less than 0.51 mm (0.020 in.) in diameter, are generally drawn in diamond dies.

Fig. 1 Typical wire-drawing die

grease, or oil is applied in the die box or die container at the time of drawing.

Wet drawing is used for manufacturing some classes of fine wire, for the light drafting of coarse wire, and for producing special finishes. The rod is generally dry drawn to a suitable size before wet drawing. The wire, with or without a preparatory heat treatment, is then cleaned and immersed in a solution of copper phosphate, iron or zinc phosphate, or a combination of these salts, depending on the finish desired. The wire thus prepared is drawn wet using a liquid lubricant.

Welds. In the continuous drawing of wire, industry practice is to weld rod coils together prior to the first draft. Ordinarily, the welds are difficult to identify unless indicated by painting, and the indicator paint can be removed from the finished wire if the customer so specifies. The welded joints will have mechanical properties that differ somewhat from those of the unaffected base metal. Therefore, samples taken for testing should not contain welds. If a test specimen is found to contain a weld, the specimen should be discarded as nonrepresentative of the wire coil and a new sample taken to establish compliance with the properties specified. If a variation in properties characteristic of welded joints between coils is objectionable, weld-free wire should be specified. It should be recognized that this restriction may limit finished wire coil weight based on the weight of the initial rod coil applied.

Finishes. The following finishes are specified to obtain smooth and clean surfaces, which may be required for functional or cosmetic reasons.

Common dry-drawn finish, sometimes referred to as bright finish, is ordinarily obtained by conventional dry-drawing practice. Many wire-drawing lubricants available in powder or viscous form consist primarily of calcium or sodium stearates.

Clean bright wire finish, which applies to low-carbon and medium-low-carbon dry-drawn wire, is a finish that is sufficiently clean and bright to ensure satisfactory performance in applications requiring spot welding and painting. Although not requiring additional drafting, clean bright wire finish does require special care in processing to provide a surface free of excess lime and lubricant. For some applications, further cleaning by the user or wire manufacturer may be necessary.

The amount of reduction during drawing is expressed as a percentage of the original cross-sectional area and is known as the overall draft or total reduction. When a rod has been reduced by cold reduction (or drawing), it is called a wire, even though many more reductions (drafts) may be necessary to reduce it to final size. This usually requires a thermal treatment between drafts. Wire produced by the single-draft drawing method refers to rod that is drawn through one die at a time, with the wire being removed from the block after each draft, until the desired diameter is achieved. Continuous drawing, which is more widely used, designates wire that is drawn through a series of dies with power-driven blocks between dies.

The drawing speed increases with each draft. The wire is coiled on the last block as in single-draft drawing or it may be taken up on a spool. With either single-draft or continuous drawing, the term direct drawing is used when the wire is drawn from acid-cleaned or mechanically descaled rod directly to finished size without thermal treatment.

Lubricants. In the drawing operation, various materials are used as lubricants to produce different finishes on the surface of the wire and to minimize die wear. Drawing can be done either with dry lubricants or wet lubricants. In dry drawing, the base for lubrication is lime, borax, phosphate, or a combination of these, applied to the surface of the cleaned rod or wire. The lubricant, soap,

Extra smooth clean bright wire finish applies to low-carbon and medium-low-carbon wire given an especially smooth, clean, bright surface by dry drawing from rod selected with respect to surface characteristics and by varying lubrication and drafting practices. This finish is intended for use where a smooth, clean surface is of primary importance in some subsequent operation, such as electroplating. A special wiredrawing practice, which requires additional inspection, selection, and, in some cases, additional draft, is necessary to produce this finish.

Coppered finish and liquor finishes are obtained by drawing rod or wire that has been immersed in a copper sulfate solution or a copper-tin sulfate solution. The solution selected depends on whether copper-colored finish, straw- or brass-colored finish, or white liquor finish is required. Coppered finish and liquor finishes can be produced by dry or wet drawing. Extra coppered finish and extra liquor finishes are normally produced with an extra smooth clean finish.

Coppered finish and liquor finishes are extremely thin. Because of the nature and thinness of these finishes, they do not provide protection against corrosion. The coppered and liquor finishes are intended for appearance and for smooth clean surfaces only. Even handling with bare hands can cause discoloration; cotton gloves should be worn. Copper or brass finishes with heavier or more resistant coatings can be provided by electroplating. Prior to drafting, it is necessary to remove the iron oxide scale from the rod. There are two common techniques used: chemical cleaning and mechanical descaling.

Cleaning and Coating. In chemical cleaning, scale and other surface contaminants are cleaned from steel wire by acid pickling followed by water rinsing. Cleaning is always followed by a supplementary coating operation (lime, borax, phosphate, or combinations of these).

Mechanical descaling by bending, wet abrasive blasting, or shotblasting can be used. This can be followed by coating with lime, borax, or soap solution, but the coating must be dry before reaching the drawing lubricant.

Lime, borax, and phosphate coating operations are performed to provide a carrier for the lubricant necessary for subsequent processing. In lime coating, practices can be varied to apply differing amounts of lime, depending on the end use. Phosphate-coated wire may have a supplementary coating of lime, borax, or a water-soluble soap. Wire is frequently cleaned and coated as a final operation, particularly where the wire has been thermally treated at finished size.

Thermal treatments for steel wire include stress relief, annealing, normalizing, patenting, and oil tempering. All thermal treatment of ferrous material involves time and temperature to provide the three phases: recovery, recrystallization, and grain growth.

Annealing is the general term applied to a variety of heat treatments for the purpose of softening the wire. Annealing commonly involves heating to a temperature above, near, or below the upper critical temperature, Ac_3 or Ac_{cm} . A number of processes are employed, all of which influence the surface finish obtained. If a particular finish is required on wire annealed at finish size, the producer should be consulted. Specific annealing processes are described below:

- Regular annealing (black annealing) is performed by heating coils of wire in a furnace, followed by slow cooling, without attempting to produce a specific microstructure or a specific surface finish
- Salt annealing is performed by immersing coils of wire in a molten salt bath, holding at the required temperature for a predetermined time, cooling in air, and removing the salt. Salt-annealed wire is not as soft as regular annealed wire and is used when maximum softness is not required or when wire slightly stiffer than regular annealed wire is desired. Salt annealing can be used as an intermediate procedure before final drawing
- Strand annealing is performed by passing wire in single strands through a bath of molten lead (lead annealing), a fluidized bed, or through open-fired furnaces (some with controlled atmospheres), followed by air cooling. Strand-annealed wire is not as soft as regular annealed wire and is used for products requiring greater strength or stiffness or as an in-process procedure in continuous operations such as wire galvanizing.
- Bright annealing of coppered finished and liquor finished wire is performed by heating and cooling the wire in a controlled atmosphere to minimize oxidation
- Lime bright annealing is performed by heating and cooling bright dry-drawn wire in a controlled atmosphere to minimize oxidation
- Spheroidize annealing involves prolonged heating at a temperature near or slightly below the lower

critical temperature, Ac_1 , followed by very slow cooling, with the object of making the carbide particles in the microstructure globular (spheroidal) in order to obtain maximum softness

Annealing in-process is performed on dry low-, medium-, and high-carbon steel wire. There are two primary levels of annealing in this type: spheroidized anneal in-process and annealed in-process. The differentiation is based on a metallographic examination of grain structure after thermal treatment. If 80% or more of the grains are spheroid, then the product is designated spheroidized in-process. This requires a longer furnace time than annealed in-process.

In producing annealed in-process wire, an annealing heat treatment (followed by a separate cleaning and coating operation) is performed at an intermediate stage of wire-drawing to produce a softer wire for applications in which direct-drawn wire would be too hard or too stiff. Annealing in-process can also be used when controlled mechanical properties are required for a specific application.

It should be noted that it is normal to clean scaled rod or wire before thermal treatment in order to avoid difficult-to-remove secondary scale formation. Such practices employ cleaned lime-coated wire and rod.

Patenting is a thermal treatment that is usually confined to medium-high-carbon and high-carbon steels. In this process, individual strands of rod or wire are heated well above the upper critical temperature (generally accepted as 900 °C, or 1650 °F) rapidly in air, molten salt, fluidized beds, or molten lead. This treatment is generally used to produce a fine pearlitic grain structure to enhance the tensile properties in subsequent wiredrawing. Patenting can be used in a continuous line in which the material is cleaned and coated.

Oil tempering is a heat treatment for high-carbon steel wire in which strands of the wire at finished size are continuously heated to an appropriate temperature above the critical temperature range, oil quenched, and subsequently passed through a stress-relieving bath. Oil tempering is used in the production of such commodities as oil-tempered spring wire, which is used in certain types of mechanical springs that are not subjected to a final heat treatment after forming. Oil-tempered wire is intended primarily for the manufacture of products that are required to withstand stresses close to the limit of the elastic range of the wire. The mechanical properties of oil-tempered wire provide resistance to permanent set under repeated and continuous stress. Oil-tempered wire is also used in applications that require abrasion resistance, such as sieves and screens.

An oxide coating of controlled thickness can be developed during the tempering of spring wire. This coating is normally left on the wire to help retain oil-base rust preventives on the surface of the wire. It also serves to prevent metal-to-metal contact during coiling or forming.

Specification Wire

There are some applications for low-carbon and medium-low-carbon steel wire that involve special requirements, such as specific tensile strength ranges or hardness limitations, the attainment of which involves special selection of steel and modification of conventional wire mill practices and/or thermal treatment (for example, annealed in-process wire). Such wire is commonly designated specification wire.

A standard specification that covers the general requirements for coarse, carbon steel round wire is ASTM A 510 (Table 5). Specification wire can be furnished with special finishes for subsequent processing, such as spot welding, electroplating, and tinning.

Table 5 Common tensile strength ranges for coarse, round specification wire

Wire diameter		Tensile strength range ^(a)	
mm	in.	MPa	ksi
0.889 to <2.69	0.035 to <0.106	207	30
2.69 to 4.50	0.106 to 0.177	172	25
>4.50	>0.177	138	20

(a) Difference between specified minimum and maximum values

Metallic Coated Wire

Metallic coatings can be applied to wire by various methods, including hot dip processes, the electrolytic process, and metal cladding by rolling metallic strip over the wire.

Aluminized wire (aluminum-coated wire) is produced by passing fluxed strands of wire through a bath of molten aluminum or aluminum alloy. The material is then rapidly cooled. This may, depending on the analysis, increase or decrease the tensile values.

Brass-plated wire is produced by passing strands or wire through an electrolytic cell containing a solution of both copper and zinc salts. Typical applications for this product are steel cord used for reinforcing automobile tires and rubber hoses and when a pleasing appearance is important. Brass-plated wire is not intended for applications requiring corrosion resistance.

Bronze-coated wire, used for tire bead reinforcement around the rim area of the tire, is produced in continuous lines by passing wires through thermal treatment to adjust physical properties, acid cleaning, and tin-copper solutions.

Galvanized wire (zinc-coated wire) is produced by passing strands of wire through a bath of molten zinc (hot dip galvanized) or through an electrolytic cell containing a solution of a zinc salt (electrogalvanized). Galvanizing gives corrosion protection to wire. The wire is usually annealed in the same operation by being passed through molten lead, molten salt, or a fluidized bed, followed by cleaning or pickling, prior to galvanizing. The general requirements for galvanized carbon steel wire are given in ASTM A 641.

The term temper as applied to galvanized wire is a reference to stiffness or resistance to bending, not to thermal treatment. It is customarily expressed as soft, medium, or hard. Tensile strengths corresponding to these three tempers are given in Table 6.

Table 6 Tensile strength ranges and limits of galvanized wire

Wire diameter		Tensile strength					
		Soft temper (maximum) ^(a)		Medium temper		Hard temper	
mm	in.	MPa	ksi	MPa	ksi	MPa	ksi
0.889 to <2.03	0.035 to <0.080	515	75	483-690	70-100	620-825	90-120
2.03 to <2.69	0.080 to <0.106	515	75	483-655	70-95	585-795	85-115
2.69 to 4.47	0.106 to 0.176	483	70	448-620	65-90	550-760	80-110
>4.47	>0.176	483	70	414-585	60-85	515-720	75-105

(a) Generally produced from maximum 0.13% C grades

Because the wire is generally strand annealed prior to zinc coating, the temper of the wire can be controlled by using different strand-annealing temperatures. Different properties can also be obtained by varying the chemical composition for a given annealing practice. The user of galvanized wire should ensure that the manufacturer has a thorough understanding of the properties, including both tensile strength and ductility, required by the end use of the wire.

Coating weights for galvanized wire vary depending on the application. The type of wire generally used for simple wire forms that do not require a minimum coating weight is variously called regular, common, single, tight wiped, ordinary, silver bright, or plain galvanized. Galvanized wire is also available with zinc coatings of specified weights: types 1, 2, and 3 and classes A, B, and C. Type 3 coating weight is the same as class A and is also called extra galvanized or double galvanized. Class B coating weight is twice class A, and class C is three times class A, as indicated in Tables 7(a), and 7(b).

Table 7(a) Zinc coating weights on galvanized wire

Wire diameter		Minimum zinc coating weight ^(a)					
		Regular coating	Type 1 coating		Type 2 coating		Type 3 coating
mm	in.		g/m ²	oz/ft ²	g/m ²	oz/ft ²	g/m ² oz/ft ²
0.889 to <1.22	0.035 to <0.048	No specified minimum weight of coating	31	0.10	92	0.30	120 0.40
1.22 to <1.57	0.048 to <0.062		46	0.15	92	0.30	120 0.40
1.57 to <1.93	0.062 to <0.076		46	0.15	110	0.35	150 0.50

1.93 to <2.03	0.076 to <0.080		61	0.20	120	0.40	180	0.60
2.03 to <2.34	0.080 to <0.092		76	0.25	140	0.45	200	0.65
2.34 to <2.51	0.092 to <0.099		92	0.30	150	0.50	210	0.70

(a) Uncoated wire surface

Table 7(b) Mandrel diameters, tests for adherence of zinc coating on galvanized wire

Wire diameter		Mandrel diameters ^(a)		
mm	in.	Regular or type 1 coating	Type 2 coating	Type 3 coating
0.889 to <1.93	0.035 to <0.076	1D	1D	2D
1.93 to <3.76	0.076 to <0.148	1D	2D	3D
3.76 to 6.35	0.148 to 0.250	2D	2D	4D
>6.35	>0.250	2D	2D	4D

(a) *D*, wire diameter

The coating weights given in Tables 7(a) and 7(b) apply to ordinary galvanized wire only; heavier coatings are applied to wire for structural applications, such as bridge wire, strand wire, and concrete-reinforcing wire. Size tolerances for galvanized wire are given in Tables 4(a), 4(b), and 4(c). Tests for coating adherence are performed by wrapping the wire on a mandrel of diameter indicated in Tables 7(a) and 7(b).

Tinned wire is produced by passing strands of wire continuously through a molten tin bath and then through tightly compressed wipes as the strands emerge from the bath. Tinned wire is commonly manufactured in three tempers: soft, medium hard, and hard. These three tempers are obtained by using the following techniques:

- Soft tinned wire is tinned after being annealed at or near finished size
- Medium-hard tinned wire is produced from thermal-treated wire

- Hard tinned wire is obtained by tinning wire that has been cold drawn to final size, usually without intermediate thermal treatment

Quality Descriptions and Commodities

Many types of steel wire have been developed for specific components of machines and equipment and for particular end uses. The unique properties of each of these types of wire are obtained by employing a specific combination of steel composition, steel quality, process thermal treatment, and cold-drawing practice.

These wires are normally grouped into broad usage categories. These categories, as well as some items in each category, are described in the following sections under their quality descriptions or commodity names.

Low-Carbon Steel Wire for General Usage

Low-carbon steel wire forms for general usage include industrial or standard-quality wire, annealed low-carbon manufacturers' wire, and merchant wire.

Industrial or standard-quality wire is produced from low- or medium-low-carbon steel, manufactured under close control in steelmaking procedures to provide internal soundness and freedom from detrimental surface imperfections for industrial applications. It is usually drawn directly from hot-rolled rod. Applications may involve specific chemical composition, but do not require specific tempers or tensile or softness limitations. The terms industrial or standard-quality wire should not be confused with or used in connection with commodity descriptions that apply to types of wire that have been developed for specific applications. Some of these are described in the AISI Steel Products Manual.

Annealed low-carbon manufacturers' wire, either black annealed or lime bright annealed, has the typical properties given in Table 8.

Table 8 Tensile strength of annealed manufacturers' wire available in coils

AISI/SAE grade	UNS grade	Maximum tensile strength	
		MPa	ksi
1006	G10060	379	55
1008	G10080	414	60

Merchant wire is annealed or soft galvanized low-carbon steel wire supplied in coils of exact weights. Black annealed wire can be supplied oiled and wiped for short-term corrosion protection.

Wire for Packaging and Container Applications

Included in wires for packaging and container applications are those designed for tying bags, baling hay and straw, binding and stapling boxes, and strapping and reinforcing shipping packages.

Baling wire for use on automatic haybaling machines is 1.93 mm (0.076 in.) or 14¹/₂ gage, diam wire made from annealed low-carbon or annealed medium-low-carbon steel. The tensile strength of baling wire is 345 to 485 MPa (50 to 70 ksi), and minimum elongation is 12% in 250 mm (10 in.). The wire is commonly produced as rewind coils having an oil-base protective coating that will not harden or become gummy when applied to the wire at the time of rewinding.

Strapping wire, sometimes called tying wire, is used for strapping and reinforcing packages such as boxes, crates, and cartons. Commonly, it is annealed wire, coppered wire, or galvanized wire. It is made to specified tensile strength requirements and must have sufficient ductility and toughness to withstand severe crimping or twisting without breaking.

Wire for Structural Applications Other Than Prestressed Concrete

This classification includes galvanized bridge wire, zinc-coated or aluminum-coated steel strand wires, and concrete-reinforcing wire.

Galvanized bridge wire is used as a component in the fabrication of strands or ropes for bridge cables, building structures, and guys. The wire is drawn from high-carbon steel wire rods with closely controlled composition ranges to achieve the desired properties. Wire size is dependent on the size of the strand or rope to be produced. Coating weight for galvanized bridge wire is class A, B, or C. These coating weights are greater than those for the corresponding designations for ordinary galvanized wire. The mechanical properties of galvanized bridge wire are given in Tables 9(a), and 9(b).

Table 9(a) Coating weights for galvanized bridge wire used as bridge strand, structural strand, bridge rope, and structural rope

Coated wire diameter		Minimum coating weight of uncoated wire surface ^(a)					
		Class A		Class B		Class C	
mm	in.	g/m ²	oz/ft ²	g/m ²	oz/ft ²	g/m ²	oz/ft ²
1.04 to 1.55	0.041 to 0.061	120	0.40	240	0.80	370	1.20
>1.55 to 2.01	>0.061 to 0.079	150	0.50	310	1.00	460	1.50
>2.01 to 2.34	>0.079 to 0.092	180	0.60	370	1.20	550	1.80
>2.34 to 2.62	>0.092 to 0.103	210	0.70	430	1.40	640	2.10
>2.62 to 3.02	>0.103 to 0.119	240	0.80	490	1.60	730	2.40
>3.02 to 3.61	>0.119 to 0.142	260	0.85	520	1.70	780	2.55
>3.61 to 4.75	>0.142 to 0.187	270	0.90	550	1.80	820	2.70

(a) Uncoated wire surface

Table 9(b) Mechanical properties of galvanized bridge wire used for bridge strand, structural strand, bridge rope, and structural rope

Diameter	Minimum	Minimum yield strength at	Total elongation under load, in 250 mm (10 in.),
----------	---------	---------------------------	--

		tensile strength ^(a)		0.7% extension under load ^(a)		percent minimum
mm	in.	MPa	ksi	MPa	ksi	
1.02 to <2.82	0.040 to <0.111	1520	220	1030	150	2.0
≥ 2.82	≥ 0.111	1520	220	1100	160	4.0
≥ 2.29	≥ 0.090	1450	210	1030	150	4.0
≥ 2.29	≥ 0.090	1380	200	965	140	4.0

(a) For actual cross section including zinc coating

Zinc-coated strand wire is used in the manufacture of galvanized steel wire strand for guy, messenger, and ground wires and for similar applications. Zinc-coated steel strand wire is commonly produced to the specified tensile strength, elongation, and weight properties of zinc coating. Each grade of strand wire is intended for use in one of the five grades of strand covered in ASTM A 475 and A 363 or in equivalent specifications.

Aluminum-coated wire is similar to zinc-coated steel strand wire except for the coating, and it is used for similar purposes. It is manufactured in conformance with ASTM A 474.

Concrete-reinforcing wire (plain, not deformed) is used either as wire or for fabrication into welded wire fabric. Generally, this wire is produced to conform to ASTM A 82, which covers mechanical property requirements, tolerances, and test procedures. Mechanical property requirements include tensile strength, yield strength, reduction in area, and bend testing. Concrete-reinforcing wire is generally furnished with a clean bright finish suitable for spot welding, except that fine wire for welded fabric is galvanized (regular coating weight) after drawing to final size. Sizes are designated by W numbers related to sectional areas.

The surface deformation lines in deformed concrete-reinforcing wire provide a mechanical anchorage in concrete, conforming to ASTM A 496. Sizes are designated by D numbers related to the average cross-sectional areas of the wires between 6.45 to 200 mm² (0.01 and 0.31 in.²).

Wire for Prestressed Concrete

Two types of uncoated round high-carbon steel wire are produced for prestressed concrete applications: cold drawn and cold drawn/stress relieved. The wire is used for linear or circular pretensioning or posttensioning concrete structural members. The stress-relieved product can be applied as a single wire or as a strand that has been stress relieved after stranding.

This product is described in American Society for Testing and Materials (ASTM) specifications as follows:

- A 648--Wire for prestressed concrete pipe
- A 416--Wire for stress-relieved strand
- A 421--Wire uncoated for linear prestressing

In North America, wires for direct linear prestressing are stress relieved.

Stress-relieved uncoated high-carbon wire is commonly used for the linear prestressing of concrete structures. It is produced in diameters of 4.88, 4.98, 6.35, and 7.01 mm (0.192, 0.196, 0.250, and 0.276 in.) to tensile strengths of 1620 to 1725 MPa (235 to 250 ksi). This wire can also be made in a low-relaxation grade. Full requirements are given in ASTM A 421. Full requirements for the stranded product are given in ASTM A 416.

After stress relieving, the inside diameters of coils are generally larger than those of drawn wire in order to prevent stress set or reintroduction of coil stress. Coil inside diameters may be as large as 200 times the wire diameter.

High-carbon wire for mechanical tensioning is commonly used for circular prestressing in the manufacture of concrete pressure pipe. Its chemical composition, tensile strength requirements, and specified wrap tests are indicated in Tables 10, 11, and 12. Full requirements are given in ASTM A 648.

Table 10 Composition of uncoated round high-carbon steel wire for tensioning by mechanical methods

Element	Chemical composition, %		
	Class I	Class II	Class III
Carbon ^(a)	0.45-0.75	0.50-0.85	0.55-0.88
Manganese ^(b)	0.60-1.10	0.60-1.10	0.60-1.10
Phosphorus	0.035 max	0.035 max	0.035 max
Sulfur	0.045 max	0.045 max	0.045 max

(a) Not varying more than 13 points in any one lot.

(b) Not varying more than 30 points in any one lot

Table 11 Strength of uncoated round high-carbon steel wire for tensioning by mechanical methods

Wire diameter		Minimum tensile strength					
		Class I		Class II		Class III	
mm	in.	MPa	ksi	MPa	ksi	MPa	ksi
4.11	0.162	1380	200	1590	231	1810	262
4.88	0.192	1320	192	1530	222	1740	252
6.35	0.250	1250	182	1450	211	1650	240

7.92	0.312	1200	174	1390	201
------	-------	------	-----	------	-----	-----	-----

Table 12 Wrap test requirements for uncoated round high-carbon steel wire for tensioning by mechanical methods

Wire diameter		Mandrel diameters ^(a)		
mm	in.	Class I	Class II	Class III
4.11 to 6.35	0.162 to 0.250	2D	2D	2D
>6.35 to 7.92	>0.250 to 0.312	2D	2D	3D

(a) *D*, wire diameter. The wire shall wind without breakage on a cylindrical mandrel of the diameter specified. When the wire diameter exceeds 7.92 mm (0.312 in.), the resistance to winding on conventional test equipment is so great that the wrap test is generally not practiced.

Wire for Electrical or Conductor Applications

Aluminum conductor steel reinforced wire, support wire, and telephone/telegraph wire are wires designed for electrical or conductor applications.

Aluminum conductor steel reinforced wire is a special commodity for the steel reinforcement of aluminum conductor cable. It is used either as a single center wire or as a multiple-wire strand and is supplied in diameters ranging from 1.27 to 4.83 mm (0.050 to 0.190 in.). This commodity is produced from either aluminum coated (ASTM B 341) or galvanized (ASTM B 498). Minimum tensile strength requirements range from 1140 to 1450 MPa (165 to 210 ksi), depending on the type and class of coating specified. Minimum yield strength and elongation, minimum coating weight, and mandrel wrap testing are additional requirements.

Support wire is a high-strength zinc-coated steel wire with a class A coating. This wire is used to support telegraph and telephone distribution lines. It is usually furnished in diameters of 2.77 to 3.76 mm (0.109 to 0.148 in.). Physical requirements are minimum tensile strength of 1310 MPa (190 ksi), minimum elongation of 2% in 250 mm (10 in.), and wrap test for ductility and adherence.

Telephone and telegraph wire is galvanized wire for signal transmission purposes. It is manufactured in several grades, for example, grades EBB and BB (ASTM A 111) and grades 85, 135, and 195 (ASTM A 326). The designations EBB and BB are abbreviations of the long-standing trade terms Extra Best Best and Best Best, which are applied to galvanized telephone and telegraph wire. All these grade designations, however, are now associated with definite values of strength and electrical resistivity. For example, EBB designates the steel wire with the lowest resistivity considered appropriate for signal transmission lines, and BB designates the steel wire with resistivity in the middle of the range appropriate for this purpose.

Rope Wire

Rope wire is produced primarily for use in the construction of wire rope. The principal grades of rope wire are level 1, 2, 3, and 4 wires, each with its own requirements with respect to tensile and torsional properties. The tensile strength requirements for these grades are shown in Fig. 2. The torsion testing of rope wire is usually done on a 203 mm (8 in.) length of the wire held between the jaws of a torsion testing machine. Minimum torsion requirements are based on the following formulas:

Level 1 ^(a) , ^(b)	$T = 34.5-25.0d^{(c)}$
Level 2 ^(d) , ^(b)	$T = 32.0-25.0d$
Level 3 ^(e) , ^(b)	$T = 29.5-25.0d$
Level 4 ^(f) , uncoated	
0.25-2.01 mm (0.010-0.079 in.)	$T = 27.5-25.0d$
2.03-4.04 mm (0.080-0.159 in.)	$T = 24.0-25.0d$
≥ 4.06 mm (0.160 in.)	By agreement between consumer and producer
Level 4 ^(f) , drawn galvanized	
0.25-2.01 mm (0.010-0.079 in.)	$T = 23.5-25.0d$
2.03-3.56 mm (0.080-0.140 in.)	$T = 20.0-25.0d$
≥ 3.58 mm (0.141 in.)	By agreement between consumer and producer

(a) Level 1 was previously designated as mild plow steel.

(b) Equation applies to both uncoated and drawn galvanized wire.

(c) T is the number of twists per 100 wire diameters of length and d is the wire diameter (in inches).

(d) Level 2, plow steel.

(e) Level 3, improved plow steel.

(f) Level 4, extra improved plow steel

Fig. 2 Tensile strength ranges for indicated rope wire grades

The latest standard-rated breaking strengths in Fig. 2 are those published in Federal Specification, Wire Rope and Strand RR W-410. In the torsion test used above, it is necessary that a specific weight be applied at the clamped end of the sample and that this weight and the revolutions per minute employed be mutually agreed upon by purchaser and supplier.

Galvanized rope wire can be galvanized either before or after drawing to finished size. When galvanizing is done at finished size, the strength requirements are 10% less than those for uncoated rope wire, and the torsion test requirements are reduced 30 to 50%, depending on size. Rope wire that is galvanized before being drawn to finished size meets the tensile and torsional properties of uncoated wire except as indicated in the above formulas for level 4 steel wire drawn after galvanizing. Wire galvanized at finished size can be produced on levels 1, 2, and 3.

Wire for Fasteners

Included in wire for fasteners is wire intended for such applications as bolts and cap screws, rivets, wood and self-tapping screws, and scrapless nuts. Depending on the application, such wire must be able to be forged, extruded, cold upset, roll or cut threaded, drilled, and hardened by suitable thermal treatment.

The type and grade of steel used in wire for fasteners depend on the requirements of the finished product and the nature of the required forming operations. Compositions range from that of 1006 grade steel, which is used for such items as common rivets, to that of a 0.55 to 0.65% C steel intended for lockwashers or screwdrivers. Low-carbon wire can be drawn from hot-rolled slow-cooled rod. Medium-carbon and high-carbon wire rod can be either annealed or spheroidized in-process.

The coating on the wire must provide sufficient lubrication in the header dies and must have the necessary lubricating qualities to prevent galling or undesirable die wear. Although lime-soap coatings are common, phosphate coatings are frequently used for more demanding applications. Producing phosphated wire may involve coating the cleaned rod or process wire with zinc phosphate and then coating with lime or borax to carry the lubricant during subsequent drawing.

It is important that the wire be internally homogeneous and free of seams and other surface imperfections. Decarburization must be held to a minimum for those products that are to be hardened by thermal treatment.

Mechanical Spring Wire for General Use

The several types of steel wire used for mechanical springs are produced in a variety of chemical compositions, but the primary consideration is that the wire have the specific properties necessary for the application. The required properties

vary with the intended use of the spring and with the problems involved in its fabrication. The factors governing the selection of spring wire include:

- The load range through which the spring must operate
- The corresponding stress range for the wire
- Weight and space limitations
- Expected life of the spring
- Temperatures and other environmental conditions to be encountered in service
- Severity of deformation to be encountered during fabrication

As stress on the wire is increased, wire with higher strength is required. Because the surface of the wire is the most highly stressed part of a spring and because spring motion gives rise to torsion effects, freedom from surface imperfections becomes increasingly important as maximum stress or required service life is increased. Surface condition is very important in music spring steel wire and is even more important in valve spring quality wire. The characteristics of springs are discussed in the article "Steel Springs" in this Volume.

There are three types of spring wire for general use:

- Hard-drawn spring wire (covered in ASTM A 227 and A 679)
- Oil-tempered spring wire (ASTM A 229)
- Spring steel wire for thermal-treated components (ASTM A 713)

Tensile strength ranges for the first two types are given in Tables 13(a) and 13(b).

Table 13(a) Tensile strength ranges for uncoated mechanical spring wire

(a) For diameters other than those shown, it is customary to determine tensile strength ranges by interpolation. Not applicable to straightened and cut wire

Table 13(b) Mandrel diameters for wrap test of uncoated mechanical spring wire

Wire diameter		Mandrel diameters ^(a)			
		Hard drawn			Oil tempered, Classes I and II
mm	in.	Class I	Class II	Class III	
0.51 to 4.11	0.020 to 0.162	1D	2D	2D	1D

(a) *D*, wire diameter. The wire shall wind without breakage on a cylindrical mandrel of the diameter specified. For ID mandrel diameter, the wire may be wound on itself. When the wire diameter exceeds 7.92 mm (0.312 in.), the resistance to winding on conventional test equipment is so great that the wrap test is generally not practiced.

Music spring steel wire is used in springs that are subject to high stresses and require good fatigue properties. Final cold drawing is commonly performed by the wet white liquor method to develop a characteristic smooth bright luster. Phosphated music wire is also common. Manufacturers employ specialized coiling tests, twist tests, torsion tests, and

bend tests to verify that the exacting requirements of this type of wire are met. Specification ASTM A 228 describes music spring steel wire in detail. Tensile strength ranges are given in Table 14.

Mechanical Spring Wire for Special Applications

Mechanical spring wire for such applications as automotive hood hinge springs, sewer augers, torque rods, and valve springs is specially designed for each application. One such material is oil-tempered valve spring quality carbon steel wire (ASTM A 230). Steel wire that is oil tempered for mechanical springs is defined in ASTM A 229 and A 679. Another is over-head door spring steel wire. Depending on design and conditions of service, making springs from the latter material may involve coiling with high initial tension and sharp bending to produce the required end formations, and the springs may be subjected to repetitive applications of high stress in service. Typical tensile strengths are shown in Table 15.

Table 15 Typical sizes and tensile strength ranges for overhead door spring steel wire

(a) Not applicable to straightened and cut wire

Upholstery Spring Construction Wire

Upholstery spring construction wire includes the several types of wire used for upholstery springs, plus the wires employed for borders and braces, hog rings, links, and frames. Upholstery spring wire is used in the manufacture of springs for mattresses, bed springs, and related applications. This type of spring wire is not intended for the manufacture of other types of springs. Upholstery spring wire is drawn from thermally treated or controlled cooled wire rod or wire. The producer determines manufacturing practice and selects specific carbon and manganese ranges within approximately 0.45 to 0.75% and 0.60 to 1.20%, respectively, to meet end-use requirements.

Upholstery spring wire is commonly produced with a dry-drawn finish and in sizes from 20 to 4 gage (0.89 to 5.72 mm, or 0.035 to 0.225 in.). Specification ASTM A 407 covers specifications for wire used in producing the various types of coil springs in common use. Table 16 lists the tensile strength ranges for one such type of wire.

Wire for Upholstery Springs. Zig-zag, square-form, and sinuous-type springs, which are extensively used in furniture, are made from hard-drawn carbon steel wire produced from controlled cooled rods, patented rods, or patented wire. These wires are commonly produced in 13 to 8 gage (2.34 to 4.11 mm, or 0.92 to 0.162 in.). Full requirements are covered in ASTM A 417. Tensile strength ranges for this type of wire are given in Table 17.

- (a) Tensile strength values for diameters not shown in this table shall conform to that shown for the next larger diameter. For example, for diameter 3.25 mm (0.128 in.), the value shall be the same as for 3.5 mm (0.135 in.).

Upholstery spring wire is also produced for Marshall spring wire types (open wound, not knotted) and lacing helical springs (ASTM A 407). Border and brace wires, generally of lower tensile values, are produced as round wire reinforcements or for cold-rolling purposes.

Wire for Other Specific Applications

Steel wire for miscellaneous specific applications includes wire for such diverse products as brush handles, clothes hangers, chains, cotter pins, screens, staples, and steel wool. Two products for which substantial quantities of wire are used are chain link fences and construction wire for automobile tires.

Chain link fence wire is a low-carbon or medium-low-carbon steel wire suitable for the production of chain link fence fabric. It is produced in diameters of 3.05, 3.76, and 4.88 mm (0.120, 0.148, and 0.192 in.) and is supplied uncoated (for zinc coating after weaving), zinc coated prior to weaving, or aluminum coated prior to weaving.

Zinc-Coated Fence Wire. Requirements for zinc-coated chain link fence fabric, which is zinc coated either before or after weaving, are covered in ASTM A 392.

Aluminum-Coated Fence Wire. Requirements for aluminum-coated chain link fence fabric are covered in ASTM A 491. This wire is always aluminum coated before weaving.

Tire bead wire is used for reinforcing the beads of pneumatic tires. Uniformity in chemical and mechanical properties and a surface finish to which rubber will adhere are essential for satisfactory performance. Tire bead wire is most commonly produced 0.94 mm (0.037 in.) in diameter and brass plated. Mechanical property tests are conducted on wire samples that have been heated for 1 h at 150 °C (300 °F). Minimum breaking strength for wire 0.94 mm (0.037 in.) in diameter is 129 kg (285 lb). In torsion testing, the wire must withstand a minimum of 58 twists in a 203 mm (8 in.) gage length.

A considerable and growing quantity of wire between 0.18 and 0.38 mm (0.0069 and 0.015 in.) in diameter is used annually for the purpose of providing cord reinforcement for radial tires. This extremely fine, high-tensile wire is produced from controlled cooled rods by drawing, followed by drawing, patenting, and a second drawing and patenting. After the second patenting operation, the wire is brass plated wet drawn and then formed into strands to be embedded into the tire rubber.

Fine Wire

Fine wire is considered to include all wire less than 0.89 mm (0.035 in.) in diameter, as well as some coarser wire up to 1.57 mm (0.062 in.) in diameter when so designated. Fine wire is commonly produced with bright, liquor, coppered, or phosphate finishes; with galvanized, tin, or cadmium coatings; and in the hard-drawn, annealed or oil-tempered conditions. Aircraft cords, broom wire, brushes, fishhooks, florist wire, hose reinforcement, paper clips, insect screens, and safety pins are examples of items produced entirely or in part from various kinds of fine wire.

Aircraft cord wire is a hard-drawn, high-tensile-strength, high-carbon steel wire designed for the manufacture of flexible cords and multiple-wire strands for aircraft controls. This type of wire is usually either tin coated or zinc coated. Common sizes range from 0.18 to 0.81 mm (0.007 to 0.032 in.) in diameter.

Hose-reinforcing wire is a hard-drawn grade commonly furnished in three tensile ranges: 2070 to 2410 MPa (300 to 350 ksi), 2240 to 2590 MPa (325 to 375 ksi), and 2410 to 2760 MPa (350 to 400 ksi). Sizes up to 0.508 mm (0.020 in.) in diameter are provided in all ranges. Sizes over 0.508 mm (0.020 in.) are furnished in the lower two ranges. The wire should be sufficiently ductile to wrap around a mandrel four times the wire diameter without fracture.

Paper clip wire is low-carbon steel wire of relatively high strength. It can be tinned or drawn after galvanizing, or it can have a liquor or copper finish. Diameters of 1.02, 0.91, and 0.80 mm (0.040, 0.036, and 0.0315 in.) are most common. In these sizes, tensile strength is about 970 MPa (140 ksi).

Safety pin wire is supplied in two grades. The high-carbon grade has a tensile strength of approximately 2210 MPa (320 ksi), while the low-carbon grade has approximately 1280 MPa (185 ksi).

Alloy Wire

The chemical compositions, quality descriptions, requirements, and tests applicable to alloy wire are described in the article "Steel Wire Rod" in this Volume. Many alloy steel wires have been developed for specific applications, which include wires for bearings, chains, and springs, and for cold-heading and cold-forging applications. Several of these are described in the following sections.

Alloy steel wire for ball and roller bearings is produced by practices that ensure internal soundness, cleanliness, uniformity of chemical composition, and a good surface. High-carbon chromium steels, such as E51100 and E52100, are commonly used for ball bearings. Roller bearings are made from high-carbon wires or from low-carbon case-hardening steels such as 4620 and 8620.

Alloy steel wire for heading, forging, and roll threading is produced by specially controlled manufacturing practices and is subjected to mill tests and inspection to ensure internal soundness, uniformity of chemical composition, and freedom from surface imperfections. These precautions are necessary to provide satisfactory heading and forging performance and proper response to subsequent thermal treatment.

Alloy steel wire for upsetting or forging is commonly produced in one of the following conditions:

- Wire drawn from spheroidize-annealed hot-rolled coils
- Wire spheroidize annealed in process
- Wire spheroidize annealed at finished size

Generally, alloy steel wire for cold heading and cold forging is spheroidize annealed in-process. This permits a light finishing draft in which the wire is given a special coating finish to facilitate cold forming. There are cases, however (especially with high-carbon wire), in which the severity of cold work requires spheroidize annealing to be done at finished size. Specification ASTM A 547 covers alloy steel wire for trimmed hexagon-head bolts.

Alloy Steel Wire for Welded Chains. Chains made from alloy steel wire are generally used for slinging, hoisting, and load-binding purposes. The wire for these chains must have high strength and good abrasion resistance. In addition, the carbon content is generally held to a maximum of 0.25% to facilitate electric welding during fabrication of the chains. Typical grades of alloy steel that satisfy these requirements are 4615, 4620, 4320, 8620, and 8622. The wire is generally furnished in the spheroidize-annealed condition so that the amount of springback between the ends of the formed links does not interfere with welding.

Alloy steel spring wire is used for the manufacture of springs intended for operation at moderately elevated temperatures. Three grades in common use are 6150 chromium-vanadium steel, SAE 9260 silicon manganese, and 9254 chromium-silicon steel, which are covered in ASTM A 231, A 232, and A 401, respectively. ASTM A 877/A 877M also covers chromium-silicon grades; ASTM A 878/A 878M covers a grade of modified chromium-vanadium steel valve spring quality wire.

The wire is commonly produced in one of four conditions: oil tempered, spheroidize annealed, annealed in-process, and patented in-process. Oil-tempered alloy spring wire, commonly produced in diameters up to 12.7 mm (0.500 in.) to tensile strength or hardness requirements, is intended for very light forming and is generally used for coiling into common types of springs. Table 18 lists tensile strength ranges for several oil-tempered wires. Annealed alloy spring wire, produced in diameters up to 15.9 mm (0.625 in.), is used for severe cold forming or coiling (when annealed in process) or for very severe cold forming or coiling (when annealed at finished size) before hardening and tempering. Tensile strength is not commonly specified for annealed wire.

Table 18 Tensile strength ranges for oil-tempered alloy steel spring wires

Wire	Chromium-vanadium spring wire, aircraft	Chromium-silicon
------	--	------------------

11.12	0.438	1340-1480	195-215	1620-1790	235-260
12.70	0.500	1310-1450	190-2110

(a) For diameters other than shown in the above table, the tensile strengths may be determined by interpolation.

Mechanical Properties: Round Wire Versus Flat Wire

Most round wire is produced and tested to required tensile ranges. With flat wire, the calculation of tensile strength is inaccurate because of the difficulty of determining the cross-sectional area as a result of the round edges and corners on the wire. Flat wire is therefore produced and tested to required hardness ranges.

Hardness and tensile properties are related, but a degree of caution must be exercised in converting one to the other. The standard conversion charts are not accurate for wire. Wire has very directional properties because its grain structure has been cold worked in only one direction. Generally, at a given hardness, wire has a higher tensile strength than that listed in the standard conversion charts.

Threaded Steel Fasteners

Revised by the ASM Committee on Threaded Steel Fasteners*

Introduction

THREADED FASTENERS for service between -50 and 200 °C (-65 and 400 °F) can be made from several different grades of steel, as long as the finished fastener meets the specified strength requirements. This article discusses the properties of threaded fasteners made from carbon and low-alloy steels containing a maximum of 0.55% C that are intended for use under the service conditions mentioned above. Guidelines are also discussed for the selection of steels for bolts (including cap screws), studs (including U-bolts), and nuts for service at the temperature range mentioned above and for service between 200 and 370 °C (400 and 700 °F). Steels used for threaded fasteners for service above 370 °C (700 °F) are also briefly discussed in this article.

Note

Frederick, Bethlehem Steel Corporation, Bar, Rod and Wire Division; Hal L. Miller, Nelson Wire Company; P.C. Hagopian, Stelco Fastener and Forging Company; and James Fox, Charter Rolling

Specification and Selection

Specifications are used to outline fastener requirements, to control the manufacturing process, and to establish functional or performance standards. Their goal is to ensure that fasteners will be interchangeable, dimensionally and functionally. The most common fastener specifications are product specifications that are set up to govern and define the quality and reliability of fasteners before they leave the manufacturer. These specifications determine what material to use; state the objectives for tensile strength, shear strength, and response to heat treatment; set requirements for environmental temperature or atmospheric exposure; and define methods for testing and evaluation. To ensure proper use of fasteners, additional specifications are necessary as a guide to proper design, application and installation. All American Society for Testing and Materials (ASTM) and Society of Automotive Engineers (SAE) specifications covering threaded fasteners require that the fastener be marked for grade identification (Table 1). Grade markings are a safety device that provide a positive check on selection, use, and inspection.

Table 1 Various ASTM and SAE grade markings for steel bolts and screws

Grade marking	Specification	Material
	SAE grade 1	Low- or medium-carbon steel
No mark	ASTM A 307	Low-carbon steel
	SAE grade 2	Low- or medium-carbon steel
	SAE grade 5	Medium-carbon steel, quenched and tempered
	ASTM A 449	
	SAE grade 5.1	Low- or medium-carbon steel, quenched and tempered
	SAE grade 5.2	Low-carbon martensite steel, quenched and tempered
	ASTM A 325, type 1	Medium-carbon steel, quenched and tempered
	ASTM A 325, type 2	Low-carbon martensite steel, quenched and tempered
	ASTM A 325, type 3	Atmospheric corrosion (weathering) steel, quenched and tempered
	ASTM A 354, grade BB	Low-alloy steel, quenched and tempered
	ASTM A 354, grade BC	Low-alloy steel, quenched and tempered
	SAE grade 7	Medium-carbon alloy steel, quenched and tempered. Roll threaded after heat treatment
	SAE grade 8	Medium-carbon alloy steel, quenched and tempered
	ASTM A 354, grade BD	Alloy steel, quenched and tempered
	SAE grade 8.2	Low-carbon martensite steel, quenched and tempered
	ASTM A 490	Alloy steel, quenched and tempered

The selection and satisfactory use of a particular fastener are dictated by the design requirements and conditions under which the fastener will be used. Consideration must be given to the purpose of the fastener, the type and thickness of materials to be joined, the configuration and total thickness of the joint to be fastened, the operating environment of the installed fastener, and the type of loading to which the fastener will be subjected in service. A careful analysis of these requirements is necessary before a satisfactory fastener can be selected. The selection of the correct fastener or fastener

system may simply involve satisfying a requirement for strength (static or fatigue) or for corrosion resistance. On the other hand, selection may be dictated by a complex system of specification and qualification controls. The extent and complexity of the system needed is usually dictated by the probable cost of a fastener failure. Failures of mechanical fasteners are discussed in *Failure Analysis and Prevention*, Volume 11 of *ASM Handbook*.

Adequate testing is the most practical method of guarding against the failure of a new fastener system for a critical application. The designer must not extrapolate existing data to a different size of the same fastener, because larger-diameter fasteners have significantly lower fatigue endurance limits than smaller-diameter fasteners made from the same material and using the same manufacturing techniques and joint system.

Strength Grades and Property Classes

Although chemical composition can be an important factor when specifying and selecting threaded fasteners for many applications (particularly when the applications require elevated-temperature service, corrosion resistance, or good hardenability characteristics with adequate toughness properties), the primary criterion in selecting threaded fasteners involves the specification of strength levels. Consequently, the grade or class of bolts, studs, and nuts are widely used to designate the various strength or performance level of threaded fasteners in the specifications developed by the Society of Automotive Engineers, the International Organization for Standardization (ISO), the American Society for Testing and Materials, and/or the Industrial Fasteners Institute (IFI). This allows the purchaser of steel bolts, studs, and nuts to select the desired strength level by specifying a grade or class in the SAE, ISO, ASTM, or IFI specifications. The producer then selects a particular steel grade that meets the broad chemical composition ranges allowed in these specifications. This enables the producers to use the most economical material consistent with their equipment and production procedures to meet the specified properties. As a result, producers have adopted substantially the same manufacturing process for a given class of product, which has resulted in a certain degree of steel grade standardization. The strength and property designations of bolts and studs are typically based on minimum tensile (breaking) strength, while the grade designations of nuts are typically based on proof stress.

The following two sections describe the commonly used ISO and SAE grade designations for steel threaded fasteners made in metric sizes or in the U.S. system of inch dimensions. Of course, other specifications (such as some of the ASTM specifications listed in Table 1) may use their own grade designation systems.

Property class designations of metric fasteners are defined in ISO R898 and SAE J1199. The commonly used property classes of steel bolts and nuts made in metric sizes are given in Tables 2 and 3, respectively. In Tables 2 and 3, the property class numbers indicate the general level of tensile strength for bolts or proof stress for nuts in megapascals. In Table 3, for example, ISO class 9 nuts have a proof stress ranging from 900 to 920 MPa. In Table 2, the number following the decimal point in a class number for a bolt or stud indicates the ratio of the yield strength to the tensile strength; for example, an ISO class 5.8 stud has a tensile strength of 520 MPa and a yield strength of 420 MPa.

Table 2 ISO property classes and SAE strength grades for steel bolts and studs (including cap screws and U-bolts)

The minimum reduction in area for specimens machined from all the grades and classes of fasteners listed is 35%.

Strength grade or property class	Nominal diameter	Proof stress ^(a)		Minimum tensile strength ^(b)		Minimum yield strength ^{(c)(d)}		Minimum elongation, % ^(e)	Maximum surface hardness, HR30N	Core hardness, HRC

(a) Determined on full-size fasteners.

(b) Determined on both full-size fasteners and specimens machined from fasteners.

(c) Determined on specimens machined from fasteners.

(d) Yield strength is stress to produce a permanent set of 0.2%.

(e) Data from ASTM F 568 or SAE J1199. Values are for fasteners with coarse threads.

(f) Yield point instead of yield strength for 0.2% offset.

(g) Class 5.8 requirements apply to bolts and screws with lengths 150 mm (6 in.) and shorter and to studs of all lengths.

(h) In SAE J1199, surface hardness shall not exceed base metal hardness by more than two points on the HRC scale or shall not exceed the maximums given.

(i) As of Sept 1983, class 12.8 and 12.9 bolts were removed from SAE J1199 because of environmentally assisted cracking of 12.8 bolts in automotive rear suspensions. Caution is advised when considering the use of class 12.8 or 12.9 bolts and screws. Capability of the bolt manufacturer, as well as the anticipated in-use environment, should be considered. High-strength products such as class 12.9 require rigid control of heat-treating operations and careful monitoring of as-quenched hardness, surface discontinuities, depth of partial decarburization, and freedom from carburization. Some environments may cause stress-corrosion cracking of nonplated as well as electroplated products.

(j) Data from SAE J429.

(k) For bolts and screws longer than 150 mm (6 in.), grade 1 requirements apply.

(l) Studs only.

(m) No. 6 screw and washer assemblies (sems) only.

(n) Bolts and screws only.

(o) Roll threaded after heat treatment

Table 3 ISO property classes and SAE strength grades for steel nuts

The following classes or grades do not normally include jam, slotted, castle, heavy, or thick nuts.

Strength grade or property class	Nominal diameter	Proof stress ^(a)		Rockwell hardness, HRC	
		MPa	ksi	Minimum	Maximum

	$>1-1\frac{1}{2}$ in.	1035	150	26	36
--	-----------------------	------	-----	----	----

- (a) Determined on full-size nuts.
- (b) Data from ASTM A 563M.
- (c) For hex and hex-flange nuts only.
- (d) Classes 853 and 1053 are not recognized in ISO standards. Classes 853 and 1053 have atmospheric corrosion resistance comparable to that of the steels covered in ASTM A 588 and A 242 (see the section "Corrosion Protection" in this article).
- (e) Data from SAE J995.
- (f) Normally applicable only to square nuts, which are normally available only in grade 2.
- (g) For UNC, 9 UN thread series.
- (h) For UNF, 12 UN threaded series and finer

Some of the ISO property class designations given in Tables 2 and 3 are used in various specifications, such as:

- SAE J1199, "Mechanical and Material Requirements for Metric Externally Threaded Steel Fasteners"
- ASTM F 568, "Specification for Carbon and Alloy Steel Externally Threaded Metric Fasteners"
- ASTM A 325M, "Specification for High-Strength Bolts for Structural Steel Joints (Metric)"
- ASTM A 490M, "Specification for High-Strength Steel Bolts, Classes 10.9 and 10.9.3, for Structural Steel Joints (Metric)"
- ASTM A 563M, "Carbon and Alloy Steel Nuts (Metric)"

However, not all of the ISO property classes are used in these specifications for metric steel threaded fasteners. Specification SAE J1199, for example, no longer allows the high-hardness fasteners (ISO bolt classes 12.8 and 12.9), because these two classes are susceptible to delayed brittle fracture in corrosive environments. This change in SAE J1199 is in response to the stress-corrosion cracking of class 12.8 bolts in automobile rear suspensions after just 2 years of service in the Snow Belt of the United States (Ref 1).

Strength grades for the U.S. system of mechanical fasteners with inch dimensions are often defined per SAE specifications. The SAE strength grades for bolts and nuts specified in inch dimensions are given in Tables 2 and 3. As can be seen in Tables 2 and 3, the SAE strength grade numbers do not directly convert to a specific strength level, although they are generally organized by strength level, that is, the greater the number, the higher the strength level. A second number, following a decimal point, is sometimes added to represent a variation of the product with the general strength level. However, this number after the decimal point does not represent a strength ratio, as in the ISO system.

In addition to the SAE specification of strength grades for steel threaded fasteners in the U.S. system, other strength grades can also be specified in ASTM standards. Table 1 shows the bolt markings for the SAE strength levels, along with a partial list of some ASTM bolt grades. When the bolt markings are the same, the SAE grade is equivalent to the ASTM

grade. In selecting approximate equivalents between the ISO classes and the various grades specified by SAE and/or ASTM, the following equivalents are suggested (for guidance purposes only) in SAE J1199:

- ISO class 4.6 is approximately equivalent to SAE J429, grade 1, and ASTM A 307, grade A
- ISO class 5.8 is approximately equivalent to SAE J429, grade 2
- ISO class 8.8 is approximately equivalent to SAE J429, grade 5, and ASTM A 449
- ISO class 9.8 has properties approximately 9% stronger than SAE J429-grade 5, and ASTM A 449
- ISO class 10.9 is approximately equivalent to SAE J429-grade 8, and ASTM a 354-grade BD

Steels for Threaded Fasteners

Many different low-carbon, medium-carbon, and alloy steel grades are used to make all the various strength grades and property classes of threaded steel fasteners suitable for service between -50 and 200 °C (-65 and 400 °F). In addition to the effects of steel composition on corrosion resistance and elevated-temperature properties, the hardenability of the steels used for threaded fasteners is important when selecting the chemical composition of the steel. As strength requirements and section size increase, hardenability becomes a major factor.

Grade 1022 steel is a popular low-carbon steel for threaded fasteners, although the low carbon content limits hardenability and therefore confines 1022 steel to the smaller diameter product sizes. For many product diameter sizes, grade 1038 steel is one of the most widely used steels for threaded fasteners up to the level of combined size and proof stress at which inadequate hardenability precludes further use. This medium-carbon steel has achieved its popularity because of excellent cold-heading properties, low cost, and availability.

Grade 1541 steel is extensively used for applications requiring hardenability greater than that of 1038 steel, but less than that of alloy steel. Figure 1 shows the depth of hardening when 19 mm ($\frac{3}{4}$ in.) diam bolts made of 1541 steel are oil quenched. Figure 1 also shows the depth of hardening with 1038 steel but with a water quench. (Figure 2 shows a more direct comparison of 1541 and 1038 hardenability.)

Fig. 1 Hardenability of 19 mm ($\frac{3}{4}$ in.) diam bolts made of 1541 steel and oil quenched. (a) Body section. (b)

Threaded section. The curves represent the average as-quenched hardnesses of fifteen 19 mm ($\frac{3}{4}$ in.) diam bolts from one heat of each grade. C is center of the bolt, 0.5R is mid-radius, S is surface. The 1038 steel bolts were water quenched; the 1541 steel bolts, oil quenched.

(a)

(b)

Steel	Cost, U.S. dollars/ton ^(a)	Largest size to quench to 42 HRC in center			
		Oil		Water	
		mm	in.	mm	in.
1038	500	3.8	0.15	1.5	0.6
10B21	520	5	0.2	18	0.7
4037	540	11	0.45	25	1
1541	530	13	0.5	28	1.1
5140	520	20	0.8	36	1.4

4140	550	44	1.75	61	2.4

(a) As of 1989

Fig. 2 Cost and hardenability relations for oil-quenched (a) and water-quenched (b) steels for cold-formed fasteners

Figure 2 shows cost-hardenability relationships for both oil- and water-quenched steels. An increase in hardenability does not necessarily mean an increase in cost per pound. Figure 2 is not intended to prescribe or imply the use of water quenching for alloy steels (which are normally oil quenched). These data are presented only to show the economic advantages of water quenching when it can be properly and successfully applied to the product being heat treated. Generally, the use of a water quench must be approached with caution, and a water quench practice is not necessarily recommended for some carbon steels (such as one of 1038 analysis) or requires careful analysis of part design, temperature control, and agitation to prevent quench cracking of low-carbon (SAE 1022) steel on an intermittent basis. Water quenching is precluded in most high-strength specifications due to uneven quenching and the resultant potential for quench cracking. For oil quenching, a large number of oil and synthetic quenchants are available. Synthetic quenchants must be monitored carefully because they can rapidly change in terms of quenching speed.

Bolt Steels. Table 4 lists the compositions for the bolt steel grades given in Table 2. As previously noted, the producer of bolts is free to use any steel within the grade and class limitations of Table 4 to attain the properties of the specified grade or class in Table 2. However, specific applications sometimes require special characteristics, and the purchaser will consequently specify the steel composition. However, except where a particular steel is absolutely necessary, this practice is losing favor. A specific steel may not be well-suited to the fastener producer's processing facilities; specification of such a steel may result in unnecessarily high cost to the purchaser.

Table 4 Chemical compositions of steel bolts and studs (including cap screws and U-bolts)

Strength grade or property class	Nominal diameter	Material and treatment	Composition, % ^(a)

8.2	$\frac{1}{4}$ - 1 in.	Low-carbon martensitic steel, fully killed, fine grain, quenched and tempered^(s)	0.15-0.25	0.048	0.058	^(h)

(a) All values are for product analysis; where a single value is shown, it is a maximum.

(b) Data from ASTM F 568.

(c) For studs only, sulfur content may be 0.33% max.

(d) For diameters through 24 mm, unless otherwise specified by the customer, the producer can use a low-carbon martensitic steel with 0.15-0.40% C, 0.74% Mn (min), 0.048% P (max), 0.058% S (max), and 0.0005% B (min.).

- (e) At producer's option, medium-carbon alloy steel can be used for diameters over 24 mm.
- (f) For studs only, sulfur content may be 0.13% max.
- (g) Requires special marking; see ASTM F 568.
- (h) 0.74% Mn (min) and 0.0005% B (min).
- (i) Available in six different types of compositions that include carbon, manganese, phosphorus, sulfur, silicon, copper, nickel, chromium, and vanadium or molybdenum in a few types. Selection of a type is at the option of the producer.
- (j) Steel for classes 10.9, 10.9.3, 12.8, and 12.9 products shall be fine grain and have a hardenability that will achieve a structure of approximately 90% martensite at the center of a transverse section one diameter from the threaded end of the product after oil quenching.
- (k) Carbon steel can be used at the option of the manufacturer for products of nominal thread diameters 12 mm and smaller. When approved by the purchaser, carbon steel can be used for products of diameters larger than 12 mm through 20 mm, inclusive.
- (l) No longer specified in SAE J1199.
- (m) Data obtained from the old (prior to Sept 1983) version of SAE J1199 and provided for information only.
- (n) Class 12.8 bolts required heat treatment in a continuous-type furnace having a protective atmosphere, and under no circumstances should heat treatment or carbon restoration be accomplished in the presence of nitrogen compounds, such as carbonitriding or cyaniding.
- (o) 0.74-1.46% Mn and 0.0005-0.003% B.
- (p) One or more of the alloying elements chromium, nickel, molybdenum, or vanadium shall be present in sufficient quantity to ensure that the specified strength properties are met after quenching and tempering.
- (q) Fine-grain steel with hardenability that will produce 47 HRC min at the center of a transverse section one diameter from the threaded end of the fastener after oil quenching (see SAE J407).
- (r) For diameters of $\frac{1}{4}$ through $\frac{3}{4}$ in., carbon steel can be used by agreement. At producer's option, 1541 steel, oil quenched and tempered, can be used for diameters through $\frac{7}{16}$ in.
- (s) Steel with hardenability that will produce 38 HRC min at the center of a transverse section one diameter from the threaded end of the fastener after quenching

Most bolts are made by cold or hot heading. Resulfurized steels are used in the manufacture of nuts, but because of their tendency to split, these grades are not routinely used in the production of headed bolts. A more recent development relates

to the use of calcium-treated steels instead of the C-1100 series steels for headed-bolt manufacture. Documented machinability data remain somewhat limited, but there are indications that the calcium-treated steels not only head well but also offer definite machinability benefits. Only a few bolts are machined from bars; these are usually of special design or the required quantities are extremely small. For such bolts, the extra cost for resulfurized grades of steel may be justified. For example, 1541 steel might be selected to make headed bolts of a specific size. If the same bolts were to be machined from bars, 1141 steel would be selected because of its superior machinability. Special bolts can usually be made more economically by machining from oversize upset blanks instead of from bars.

Stud Steels. The chemical compositions of studs (and U-bolts, which are basically studs formed into a U-shape) are given in Table 4; special modifications that apply to studs can be found in the footnotes. Because studs (and U-bolts) are not headed, it is not essential to restrict sulfur. It may be noted that grade 2 and class 5.8 permit 0.33% maximum sulfur, while grade 5 and classes 8.8 and 9.8 permit 0.13% maximum sulfur.

Stud (or U-bolt) threads, however, are not necessarily cut, but can be rolled for economy and good thread shape. A smaller-diameter rod must be used to roll a specific thread size than to cut the same thread size from rod. For example, a $\frac{1}{2}$ -13 thread could be cut from a rod 12.7 mm (0.500 in.) in diameter; a smaller diameter rod would be used to roll the same size threads. Grades 4 and 8.1 are made from a medium-carbon steel and obtain their mechanical properties not from quenching and tempering but from being drawn through a die with special processes. They are particularly suitable for studs because these materials cannot readily be formed into bolts.

Selection of Steel for Bolts and Studs. The following guidelines should be considered when selecting steel for bolts and studs (including cap screws and U-bolts):

- Depending on the capabilities of a facility, bolts up to 305 mm (12 in.) in length and 32 mm ($1\frac{1}{4}$ in.) in diameter can be cold headed. For shops not having this or similar specialized equipment, bolts more than 150 mm (6 in.) in length or more than 19 mm ($\frac{3}{4}$ in.) in diameter may have to be hot headed
- Strength requirements for steels for grade 1 bolts can be met with hot-rolled low-carbon steels
- Depending on the manufacturing method, the strength requirements for steels for grade 2 bolts ranging from 19 to 32 mm ($\frac{3}{4}$ to $1\frac{1}{4}$ in.) or less in diameter can be met with cold-drawn low-carbon steels; sizes larger than this diameter range of 19 to 32 mm ($\frac{3}{4}$ to $1\frac{1}{4}$ in.) require hot-rolled low-carbon steel only if the bolt is hot headed, but may be made of cold-finished material
- Grade 4 fasteners (studs only) require a cold-finished medium-carbon steel, specially processed to obtain higher-than-normal strength. Resulfurized steels are acceptable
- Grade 5 bolts and studs require quenched and tempered steel. The choice among carbon, 1541, and alloy steel will vary with the hardenability of the material, the size of the fastener, and the quench employed. Cost favors the use of carbon steel, including 1541; however, the possibility of quench cracking and excessive distortion determines the severity of the quench that can be used. The threading practice (before or after hardening) also determines the severity of quench that can be used if quench cracks in the threads are to be avoided. Generally, the use of a water quench must be approached with caution
- Fasteners made to grade 7 and 8 specifications normally require medium-carbon, fine-grain alloy steel. This steel is selected on a hardenability basis so a minimum of 90% martensite exists at the center after oil quenching. SAE J429 requires oil quenching of these two grades
- Fasteners of SAE grades 5.2 and 8.2 are made from low-carbon martensitic boron steels. These steels (and the low-carbon versions of ISO classes 8.8, 9.8, and 10.9 in Table 4) are readily formed because of the low carbon content, yet the boron gives them relatively high hardenability. Fasteners of these grades are hardened in oil or water, then tempered at minimum temperatures of 425 °C (800 °F) for the 8.2 grade and 340 °C (650 °F) for the 5.2 grade. Grades 5.2 and 8.2 are expected to offer the same mechanical properties as the corresponding nonboron grades 5 and 8 (Fig. 3), but grades 5.2 and 8.2 may have slightly better toughness and ductility than the medium-carbon 5 and 8 grades at comparable hardness levels. *Caution: Grades 5.2 and 8.2 should be used with caution due to the potential for tempering (softening) at lower temperatures than grade 5 or 8 fasteners*

- ISO bolt class 12.8 is also made from a low-carbon martensitic (boron) steel. *Caution: However, this class of bolt is susceptible to stress-corrosion cracking and should be used with caution. This bolt class is no longer specified in SAE J1199 because of failures in automobiles after just two years of service (Ref 1).*
- *Caution: ISO bolt class 12.9 has also been removed from SAE J1199. Caution is advised when considering the use of class 12.9 bolts and screws because, like the 12.8 class, the 12.9 class is susceptible to stress-corrosion cracking.* The capability of the bolt manufacturer, as well as the anticipated in-use environment, should be considered for both the 12.8 and 12.9 classes. High-strength products such as class 12.9 require rigid control of the heat-treating operations and careful monitoring of as-quenched hardness, surface discontinuities, depth of partial decarburization, and freedom from carburization. Some environments may cause stress-corrosion cracking of nonplated as well as electroplated products
- For service temperatures of 200 to 370 °C (400 to 700 °F), specific bolt steels are recommended (Table 5) because relaxation is an influencing factor at these temperatures. Although other steels will fulfill requirements for the tabulated conditions, those listed are the commonly used grades. Only medium-carbon alloy steels are recommended; in all instances, they should be quenched and tempered

Fig. 3 Tensile and impact properties of fully quenched and tempered boron steels superimposed on normal expectancy bands for medium-carbon low-alloy steels without boron

Table 5 Recommended steels for bolts to be used at temperatures between 200 and 370 °C (400 and 700 °F)

All selections are based on a minimum tempering temperature of 455 °C (850 °F).

Bolt diameter		Steel recommended for a proof stress (at room temperature) of:		
mm	in.	520 MPa (75 ksi)	690 MPa (100 ksi)	860 MPa (125 ksi)
6.3-19	$\frac{1}{4}$ - $\frac{3}{4}$	1038	4037	4037
19-32	$\frac{3}{4}$ - $1\frac{1}{4}$	1038	4140	4140
32-50	$1\frac{1}{4}$ - 2	4140	4140	4145

Nut Steels. The selection of steel for nuts is less critical than for bolts. The nut is usually not made from the same material as the bolt. Table 6 gives the chemical composition requirements for each property grade and class of steel nut shown in Table 3.

Table 6 Chemical compositions of steel nuts

Strength grade or property class	Composition, % ^(a)			
	C (max)	Mn (min)	P (max)	S (max)
SAE strength grades ^(b)				
2	0.47	...	0.12 ^(c)	0.15^(d)
5	0.55	0.30	0.05 ^{(e)(f)}	0.15^{(d)(f)}
8	0.55	0.30	0.04	0.05^(g)
ISO property classes ^(h)				
5 ⁽ⁱ⁾ and 9	0.55	...	0.04	0.15^{(c)(d)}
8S	0.55	...	0.04	0.15
10	0.55	0.30	0.04	0.05^(j)
853 ^(k)	See ASTM A 563M.			
1053 ^(k)	See ASTM A 563M.			

12	0.20-0.55	0.60	0.04	0.05^(j)
-----------	------------------	-------------	-------------	---------------------------

(a) All values for heat analysis.

(b) Data from SAE J995.

(c) Resulfurized and rephosphorized material is not subject to rejection based on check analysis for sulfur.

(d) If agreed, sulfur can be 0.23% max.

(e) For acid bessemer steel, phosphorus can be 0.13% max.

(f) If agreed, phosphorus can be 0.12% max and sulfur can be 0.35% max, provided manganese is 0.70% min.

(g) If agreed, sulfur can be 0.33% max, provided manganese is 1.35% min.

(h) Data from ASTM A 563M.

(i) If agreed, free-cutting steel having maximums of 0.34% S, 0.12% P, and 0.35% Pb can be used.

(j) If agreed, sulfur can be 0.15% max with a minimum of 1.35% Mn.

(k) Corrosion-resistant grades are not included in ISO classifications. Class 853 is used with bolt grade 8.8.3 and has a selection of steel compositions at the option of the manufacturer. Class 1053 is used with bolt grade 10.9.3.

Lower-strength nuts (such as grades 2 and 5) are not heat treated. However, higher-grade nuts (such as grade 8) can be heat treated to attain specified hardness.

Nuts are machined from bar stock, cold formed or hot formed, depending on configuration and production requirements. Size and configuration are usually more important than the material from which the nuts are made.

The bolt is normally intended to break before the nut threads strip. Regular hex nut dimensions are such that the shear area of the threads is greater than the tensile stress area of the bolt by more than 100%. Consequently, low-carbon steel nuts are customarily used even when the bolts are made of much higher strength material.

Low-carbon steel nuts are usually heat treated to provide mar resistance to the corners of the head or to the clamping face. Light case carburizing or carbonitriding is often employed to improve mar resistance.

When nuts are to be quenched and tempered, the steel must have the appropriate hardenability. Increasing the amounts of carbon and manganese or adding other alloying elements to provide increased hardenability will decrease the suitability of the material for cold forming. For this reason, low-carbon boron steels are widely used for quenched and tempered high-strength nuts. The low carbon content permits easy cold forming, while the boron enhances hardenability. Threading can be done before or after heat treatment, depending on the class of thread fit required and the hardness of the heat-treated nut.

Because the selection of steel for nuts is not critical, practice varies considerably. A common practice is to use steels such as 1108, 1109, 1110, 1113, or 1115, cold formed or machined from cold-drawn bars, for grade 2 nuts. Grade 5 nuts are commonly made from 1035 or 1038 steels, cold formed from annealed bars, cold drawn and stress relieved, or quenched and tempered. Grade 8 nuts are formed from low-carbon boron steels, then quenched and tempered.

Corrosion Protection

The most commonly used protective metal coatings for ferrous metal fasteners are zinc, cadmium, and aluminum. Tin, lead, copper, nickel, and chromium are also used, but only to a minor extent and for very special applications. In many cases, however, fasteners are protected by some means other than metallic coatings. They are sometimes sheltered from moisture or covered with a material that prevents moisture from making contact, thus drastically reducing or eliminating corrosion. For fasteners exposed to the elements, painting is universally used.

The low-alloy high-strength steel conforming to ASTM A 242 and A 588 forms its own protective oxide surface film. This type of steel, although it initially corrodes at the same rate as plain carbon steel, soon exhibits a decreasing corrosion rate, and after a few years, continuation of corrosion is practically nonexistent. The oxide coating formed is fine textured, tightly adherent, and a barrier to moisture and oxygen, effectively preventing further corrosion. Plain carbon steel, on the other hand, forms a coarse-textured flaky oxide that does not prevent moisture or oxygen from reaching the underlying noncorroded steel base.

The 853 and 1053 class nuts (Table 3) and bolt classes 8.8.3 and 10.9.3 (Table 4) have corrosion resistance characteristics similar to those of steels conforming to ASTM A 242 and A 588. These weathering steels are suitable for resisting atmospheric corrosion and have an atmospheric corrosion resistance approximately two times that of carbon structural steel with copper. However, these weathering steels are not recommended for exposure to highly concentrated industrial fumes or severe marine conditions, nor are they recommended for applications in which they will be buried or submerged. In these environments, the highly protective oxide does not form properly, and corrosion is similar to that for plain carbon steel.

Zinc Coating. Zinc is the coating material most widely used for protecting fasteners from corrosion. Electroplating and zinc phosphating are the two most frequently used method of application, followed by hot dipping and, to a minor extent, mechanical plating.

Hot dipping, as the name implies, involves immersing parts in a molten bath of zinc. Hot dip zinc coatings are sacrificial by electrochemical means, and these coatings for fasteners are covered in ASTM A 394. Zinc electroplating of fasteners is done primarily for appearance, where thread fit is critical, where corrosion is not expected to be severe, or where life expectancy is not great.

Specification ASTM B 633 for electrodeposited zinc coatings on steel specifies three coating thicknesses: GS, 25 μm (0.0010 in.); LS, 13 μm (0.0005 in.); and RS, 4 μm (0.00015 in.). These electrodeposited coatings are often given supplemental chromate coatings to develop a specific color and to enhance corrosion resistance. The corrosion life of a zinc coating is proportional to the amount of zinc present and chromate finish; therefore, the heaviest electrodeposited coating (GS) would have only about half the life of a hot dip galvanized coating.

Mechanical (nonelectrolytic) barrel plating is another method of coating fasteners with zinc. Coating weight can be changed by varying the amount of zinc used and the duration of barrel rotation. Such coatings are quite uniform and have a satisfactory appearance.

Cadmium coatings are also applied to fasteners by an electroplating process similar to that used for zinc. These coatings are covered in ASTM A 165. As is true for zinc, cadmium corrosion life is proportional to the coating thickness. The main advantage of cadmium over zinc is its much greater resistance to corrosion in marine environments and uniformity of torque-tension relationship. Cadmium-plated steel fasteners are also used in aircraft in contact with aluminum because the galvanic characteristics of cadmium are more favorable than those of zinc. Chromate coatings are also used over cadmium coatings for the reasons given for zinc-plated fasteners.

Aluminum coating on fasteners offers the best protection of all coatings against atmospheric corrosion. Aluminum coating also gives excellent corrosion protection in seawater immersion and in high-temperature applications.

Aluminum coatings are applied by hot dip methods at about 675 to 705 °C (1250 to 1300 °F). Aluminum alloy 1100 is usually used because of its general all-around corrosion resistance. As with any hot dip coating, a metallurgical bond is formed that consists of an intermetallic alloy layer overlaid with a coating of pure bath material.

Aluminum coatings do not corrode uniformly, as do zinc and cadmium coatings, but rather by pitting. In some cases, these pits may extend entirely through the coating to the base metal; in others, only through the overlay to the intermetallic layer. Pits, which may occur in a part soon after exposure, sometimes discolor the coated surface but cause little damage. The complex aluminum and iron oxide corrosion product seals the pits, and because the corrosion product is tightly adherent and impervious to attack, corrosion is usually limited. There is little tendency for corrosion to continue into the ferrous base, and there is none for undercutting and spalling of the coating.

Aluminum coatings will protect steel from scaling at temperatures up to about 540 °C (1000 °F); the aluminum coating remains substantially the same as when applied, and its life is exceptionally long. Above 650 °C (1200 °F), the aluminum coating diffuses into the steel to form a highly protective aluminum-iron alloy. This diffusing or alloying is time-temperature dependent; the higher the temperature, the faster the diffusion. However, scaling will not take place until all the aluminum is used up, which may take a thousand or more hours even at temperatures as high as 760 °C (1400 °F).

The prevention of galling at elevated temperatures is another characteristic of aluminum coatings. Stainless steel fasteners for use at 650 °C (1200 °F) have been aluminum coated just to prevent galling. Coated nuts can be removed with an ordinary wrench after many hours at these temperatures, which is impossible with uncoated nuts.

Fastener Performance at Elevated Temperatures

Selection of fastener material is perhaps the single most important consideration in elevated-temperature design. The basic design objective is to select a bolt material that will give the desired clamping force at all critical points in the joint.

Time- and Temperature-Related Factors. To achieve the basic design objective mentioned above, it is necessary to balance the three time- and temperature-related factors (modulus, thermal expansion, and relaxation) with a fourth factor--the amount of initial tightening or clamping force. These three time- and temperature-related factors affect the elevated-temperature performance of fasteners as follows.

Modulus of Elasticity. As temperature increases, the modulus of elasticity decreases; therefore, less load (or stress) is needed to impact a given amount of elongation (or strain) to a material than at lower temperatures. This means that a fastener stretched a certain amount at room temperature to develop preload will exert a lower clamping force at higher temperature.

Coefficient of Expansion. With most materials, the size of the part increases as the temperature increases. In a joint, both the structure and the fastener increases in size with an increase in temperature. If the coefficient of expansion of the fastener exceeds that of the joined material, a predictable amount of clamping force will be lost as temperature increases. Conversely, if the coefficient of expansion of the joined material is greater, the bolt may be stressed beyond its yield or even fracture strength, or cyclic thermal stressing may lead to thermal fatigue failure. Thus, matching of materials in joint design can ensure sufficient clamping force at both room and elevated temperatures without overstressing the fastener.

Relaxation. In a loaded bolt joint at elevated temperature, the bolt material will undergo permanent plastic deformation (creep) in the direction of the applied stress. This phenomenon, known as relaxation in loaded-joint applications, reduces the clamping force with time. Relaxation is the most important of the three time- and temperature-related factors and is discussed in more detail in the article "Elevated-Temperature Properties of Ferritic Steels" in this Volume.

Bolt Steels for Elevated Temperatures. Table 5 lists the recommended steels for bolts to be used at temperatures between 200 and 370 °C (400 and 700 °F). For higher temperatures up to 480 °C (900 °F), other alloy steels are used. For example, the medium-alloy chromium-molybdenum-vanadium steel conforming to ASTM A 193, grade B 16, is a commonly used bolt material in industrial turbine and engine applications to 480 °C (900 °F). An aircraft version of this steel, AMS 6304, is widely used in fasteners for jet engines. The 5% Cr tool steels, most notably H11, are also used for fasteners having a tensile strength of 1500 to 1800 MPa (220 to 260 ksi). They retain excellent strength through 480 °C (900 °F).

For temperatures above 480 °C (900 °F), heat-resistant alloys or superalloys are used for bolt materials. From 480 to 650 °C (900 to 1200 °F), corrosion-resistant alloy A-286 is used. Alloy 718, with a room-temperature tensile strength of 1240

MPa (180 ksi), has some applications in this temperature range. The nickel-base alloys René 41, Waspaloy, and alloy 718 can be used for most applications in the temperature range of 650 to 870 °C (1200 to 1600 °F).

Coatings for Elevated Temperatures. At moderate temperatures, where cadmium and zinc anticorrosion platings might normally be used, the phenomenon of stress alloying becomes an important consideration. Conventional cadmium plating, for example, is usable only to 230 °C (450 °F). At somewhat above that temperature, the cadmium is likely to melt and diffuse into the base material along the grain boundaries, causing cracking by liquid-metal embrittlement, which can lead to rapid failure. For corrosion protection of high-strength alloy steel fasteners used at temperatures between 230 and 480 °C (450 and 900 °F), special nickel-cadmium coatings such as that described in AMS 2416 are often used. At extremely high temperatures, coatings must be applied to prevent oxidation of the base material.

Effect of Thread Design on Relaxation. Fastener-manufacturing methods can also influence bolt performance at elevated temperature. The actual design and shape of the threaded fastener are also important, particularly the root of the thread. A radiused thread root is a major consideration in room-temperature design, being a requisite for good fatigue performance. However, at elevated temperature, a generously radiused thread root is also beneficial in relaxation performance. Starting at an initial preload of 483 MPa (70 ksi), a Waspaloy stud with square thread roots lost a full 50% of its clamping force after 20 h, with the curve continuing downward, indicating a further loss. A similar stud made with a large-radiused root lost only 36% of preload after 35 h.

Fastener Tests

The fastener manufacturer must perform periodic tests of the product to ensure that properties are maintained within specified limits. Guidelines for testing are provided in ASTM F 606 and in SAE J429 (bolts and studs in U.S. inch sizes), J995 (nuts in U.S. inch sizes), and J1216 (test methods for metric threaded fasteners). When requested in writing by the purchaser, the manufacturer will furnish a copy of a certified test report.

The most widely accepted method of determining the strength of full-size bolts and studs is a wedge tensile test for minimum tensile (breaking) strength. Testing of nuts involves a proof stress testing. Proof stress testing of bolts and studs is also performed before the test for ultimate wedge tensile strength.

The wedge tensile test of bolts accentuates the adverse conditions of bolts assembled under misalignment; therefore, it is also the most widely used quality control test for ultimate strength and head-to-body integrity and ductility. The test is performed by placing the wedge under the bolt head and, by means of suitable fixtures, stressing the bolt to fracture in a tensile test machine. To meet the requirements of the test, the tensile fracture must occur in the body, or threaded section, with no fracture at the junction of the body and head. In addition, the breaking strength should meet specified minimum strength requirements. Details of this test are given in ASTM F 606 and SAE J429.

The number of exposed threads between the bolt shank and the beginning of the nut or testing fixture influences the recorded tensile strength for both coarse-thread and fine-thread bolts. A typical variation of breaking strength with number of exposed threads is plotted in Fig. 4. The data are for $\frac{3}{4}$ in. diam SAE grade 5 bolts. Because of this variation, the number of exposed threads should be specified for wedge tensile testing of bolts and other threaded fasteners; generally, six exposed threads are specified.

Fig. 4 Variation of breaking strength with number of exposed threads for $\frac{3}{4}$ in. diam SAE grade 5 bolts.

The proof stress of a bolt or stud is a specified stress that the bolt or stud must withstand without detectable permanent set. For purposes of this test, a bolt or stud is deemed to have incurred no permanent set if the overall length after application and release of the proof stress is within ± 0.013 mm (± 0.0005 in.) of its original length. Length measurements are ordinarily made to the nearest 0.0025 mm (0.0001 in.). Because bolts and studs are manufactured in specific sizes, the proof stress values are commonly converted to equivalent proof load values, and it is the latter that are actually used in testing full-size fasteners. To compute proof load, the stressed area must first be determined. Because the smallest cross-sectional area is in the threads, the stressed area is computed as follows:

$$A_s (\text{in}^2) = 0.7854 \left(D - \frac{0.9743}{N} \right)^2 \quad (\text{Eq 1})$$

where A_s is the mean equivalent stress area in square inches, D is the nominal diameter in inches, and N is the number of threads per inch. The equivalent formula for metric threads is:

$$A_s (\text{mm}^2) = 0.7854 (D - 0.9382P)^2 \quad (\text{Eq 2})$$

where A_s is the mean equivalent stress area in millimeters, D is the nominal diameter in millimeters, and P is the thread pitch in millimeters.

For example, $\frac{1}{2}$ in. diam bolts made to SAE grade 5 requirements have values of mean equivalent stress area for coarse threads (13 threads per inch) and fine threads (20 threads per inch) equal to 0.1419 in.² and 0.1599 in.², respectively, according to Eq 1. These bolts must withstand a proof stress of 585 MPa (85 ksi) without a detectable difference between the initial length and the length after the proof load has been applied and released. For coarse threads, this requires a proof load of 53.6 kN (12,060 lb); for fine threads, the proof load is 60.5 kN (13,600 lb).

The proof stress of a nut is determined by assembling it on a hardened and threaded mandrel or on a test bolt conforming to the particular specification. The specified proof load for the nut is determined by converting the specified proof stress, using the mean equivalent stress area calculated for the mandrel or test bolt. This proof load is applied axially to the nut by a hardened plate, as shown in Fig. 5. The thickness of the plate is at least equal to the diameter of the mandrel or test bolt. The diameter of the hole in the plate is a specified small amount greater than that of the mandrel or test bolt diameter. To demonstrate acceptable proof stress, the nut must resist the specified proof load without failure by stripping or rupture, and it must be removable from the mandrel or test bolt by hand after initial loosening.

Fig. 5 Test setup for the proof testing of nuts

Details relating to the prescribed proof stress tests and other requirements for threaded steel fasteners of various sizes in both coarse and fine threads are available in SAE J429 and J995 for fasteners made to SAE strength grades or ISO 898 for fasteners made to ISO property classes. Additional information is also available in ASTM F 606.

Mechanical Properties

The major mechanical properties of fasteners include:

- Tensile (breaking) strength with a static load
- Hardness
- Fatigue strength with a dynamic loading
- Resistance to stress-corrosion cracking or other forms of environmentally induced cracking, such as hydrogen embrittlement and liquid-metal embrittlement

The following sections briefly review these mechanical properties of threaded steel fasteners.

Strengths With Static Loads. Table 2 and 3 list the specified mechanical properties of the commonly used SAE strength grades and ISO property classes of steel bolts, studs, and nuts. As previously noted, the grades or classes of these specifications are based on tensile strength for bolts and studs or proof stress for nuts.

Grade 1038 steel is one of the most widely used steels for threaded fasteners. Typical distributions of tensile properties for bolts and cap screws made from 1038 steel, as evaluated by the wedge tensile test, are shown in Fig. 6. These data were obtained from one plant and represent tests from random lots of SAE grade 5 fasteners. The three histograms in Fig. 6 show three distributions typical of grade 5 fasteners. No significance should be attached to the apparent difference between average values, especially for the two hex-head bolts of different lengths. Specifications require only that bolt strength exceed a specified minimum value, not that bolts of different sizes have statistically equivalent average strengths.

Fig. 6 Typical strength distributions for 10° wedge tests of 1038 steel cap screws and bolts

Hardness Versus Tensile Strength. To ensure freedom from the effects of decarburization and nonrepresentative cooling rates during the quench, there is really only one preferred location for checking hardness. This location is the mid-radius of a transverse section taken one diameter from the threaded end of the bolt (Fig. 7). If the hardness tests are not taken at this location, then greater scatter will occur in the relation between hardness and tensile strength. For example, hardness tests taken at the bolt head will probably result in more scatter because the greater thermal mass of the bolt head products differences in quench efficiency and may result in incomplete hardening.

Fig. 7 Relation of hardness and tensile strength for SAE grade 5 bolts made of 1038 steel

The bolt shown in Fig. 7 was made from one heat of 1038 steel of the following composition: 0.38% C, 0.74% Mn, 0.08% Si 0.025% P, 0.040% S, 0.08% Cr, 0.07% Ni, and 0.12% Cu. The bolt was quenched in water from 845 °C (1550 °F) and tempered at different temperatures in the range 365 to 600 °C (690 to 1110 °F) to produce a range of hardness of 20 to 40 HRC.

Figure 8 shows the results of a cooperative study in which eight laboratories tested a large number of bolts made from a single heat of 1038 steel. There were eight different lots of bolts, each heat treated to a different hardness level. Each of

the eight laboratories tested bolts from all eight lots. Hardness readings were taken on a transverse section through the threaded portion of the bolt at the mid-radius of the bolt. The transverse section was located one diameter from the threaded end of the bolt.

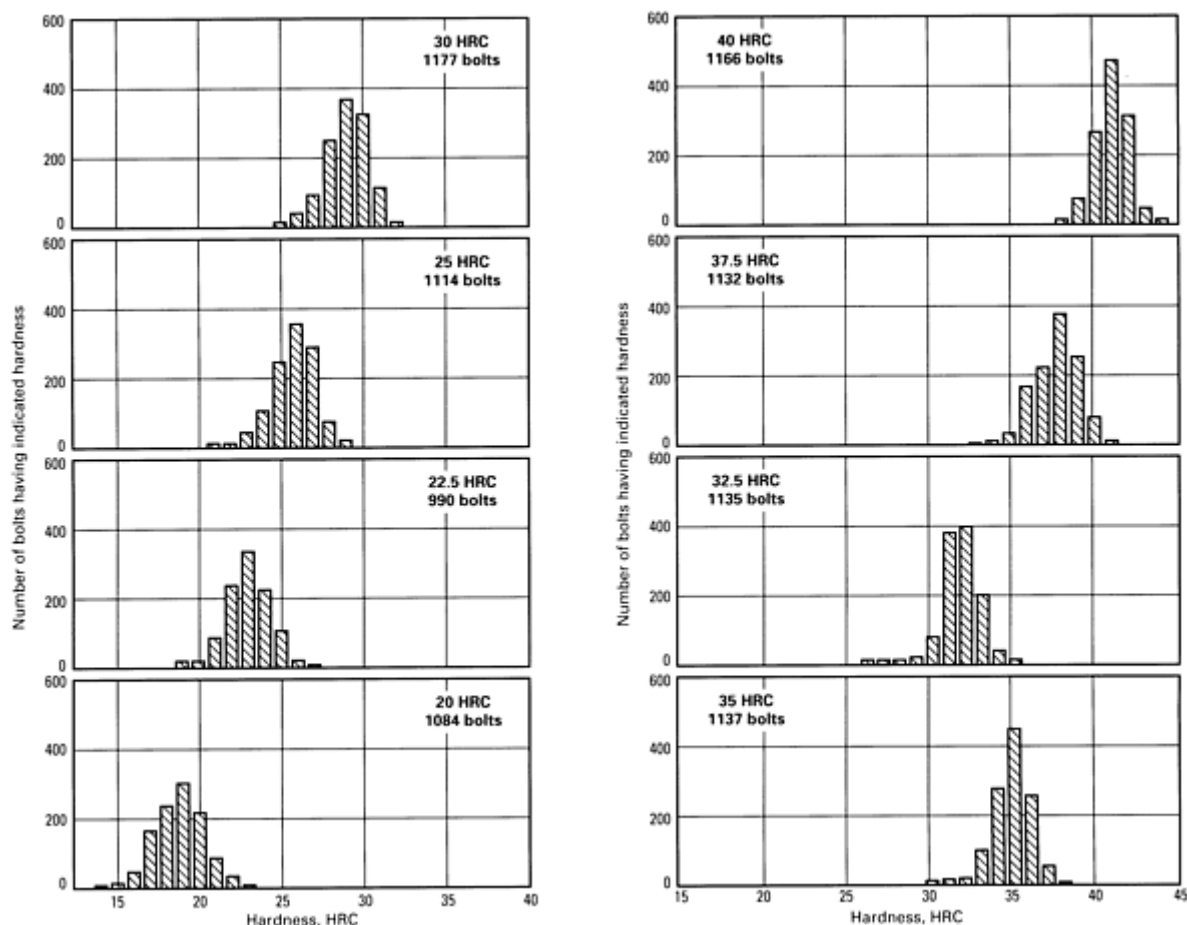

Fig. 8 Hardness distribution for eight lots of 1038 steel bolts. Bolts, 13 mm ($\frac{1}{2}$ in.) in diameter, were all made from one heat of steel. The bolts were heat treated in one plant to eight different levels of nominal hardness. Tests were made in the originating plant and in seven other laboratories.

Fatigue Failures. Fatigue is one of the most common failure mechanisms of threaded fasteners, particularly if insufficient tightening of the fasteners results in flexing. To eliminate this cause of fatigue fracture at room temperature; the designer should specify as high an initial preload as practical. Higher clamping forces make more rigid joints and therefore reduce the rate of fatigue crack propagation from flexing. The optimum fastener-torque values for applying specific loads to the joint have been determined for many high-strength fasteners. However, these values should be used with caution, because the tension produced by a selected torque value depends directly on the friction between the contacting threads. The use of an effective lubricant on the threads may result in overloading of the fastener, while the use of a less effective lubricant may result in a loose joint. With proper selection of materials, proper design of bolt-and-nut bearing surfaces, and the use of locking devices, the assumption is that the initial clamping force will be sustained during the life of the fastened joint. This assumption cannot be made in elevated-temperature design. At elevated temperature, the induced bolt load will decrease with time as a result of creep.

Fatigue Strength. The factors affecting the fatigue strength of threaded fasteners include surface condition, mean stress, stress range, and the grain pattern at the head-to-shank fillet. If bolts made of two different steels have equivalent hardnesses throughout identical sections, their fatigue strengths will be similar (Fig. 9) as long as other factors such as mean stress, stress range, and surface condition are the same. If the results of fatigue tests on standard test specimens were interpreted literally, high-carbon steels would be selected for bolts. Actually, steels of high carbon content ($>0.55\%$ C) are unsuitable because they are notch sensitive.

Fig. 9 Fatigue data for 1040 and 4037 steel bolts. The bolts ($\frac{3}{8}$ by 2 in., 16 threads to the inch) had a hardness of 35 HRC. Tensile properties of the 1040 steel at three-thread exposure were yield strength, 1060 MPa (154 ksi); tensile strength (axial), 1200 MPa (175 ksi); tensile strength (wedge), 1190 MPa (173 ksi). For the 4037 steel: yield strength, 1110 MPa (161 ksi); tensile strength (axial), 1250 MPa (182 ksi); tensile strength (wedge), 1250 MPa (182 ksi)

The principal design feature of a bolt is the threaded section, which establishes a notch pattern inherent in the part because of its design. The form of the threads, plus any mechanical or metallurgical condition that also creates a surface notch, is much more important than steel composition in determining the fatigue strength of a particular lot of bolts. Some of these factors are discussed below.

Causes and Prevention of Fatigue Crack Initiation. The origin of a fatigue crack is usually at some point of stress concentration, such as an abrupt change of section, a deep scratch, a notch, a nick, a fold, a large inclusion, or a marked change in grain size. Fatigue failures in bolts often occur in the threaded section immediately adjacent to the edge of the nut (or mating part) on the washer side, at or near the first thread inside the nut (or mating part). This area of stress concentration occurs because the bolt elongates as the nut is tightened, thus producing increased loads on the threads nearest the bearing face of the nut, which add to normal service stresses. This condition is alleviated to some extent by using nuts of a softer material that will yield and distribute the load more uniformly over the engaged threads. Significant additional improvement in fatigue life is also obtained by rolling (cold working) the threads rather than cutting them and also by rolling threads after heat treatment rather than before.

Other locations of possible fatigue failure of a bolt under tensile loading are the thread runout and the head-to-shank fillet. Like the section of the bolt thread described in the previous paragraph, these two locations are also areas of stress concentration. Any measures that decrease stress concentration can lead to improved fatigue life. Typical examples of such measures are the use of UNJ increased root radius threads (see MIL-S-8879A) and the use of internal thread designs that distribute the load uniformly over a large number of bolt threads. Shape and size of the head-to-shank fillet are important, as is a generous radius from the thread runout to the shank. In general, the radius of this fillet should be as large as possible while at the same time permitting adequate head-bearing area. This requires a design trade-off between the head-to-shank radius and the head-bearing area to achieve optimum results. Cold working of the head fillet is another common method of preventing fatigue failure because it induces a residual compressive stress and increases the material strength.

Several other factors are also important in avoiding fatigue fracture at the head-to-shank fillet. The heads of most fasteners are formed by hot or cold forging, depending on the type of material and size of the bolt. In addition to being a relatively low-cost manufacturing method, forging provides smooth, unbroken grain flow lines through the head-to-shank fillet, which closely follows the external contour of the bolt (Fig. 10) and therefore minimizes stress raisers, which promote fatigue cracking. In the hot forging of fastener heads, temperatures must be carefully controlled to avoid overheating, which may cause grain growth. Several failures of 25 mm (1 in.) diam type H-11 airplane-wing bolts quenched and tempered to a tensile strength of 1800 to 1930 MPa (260 to 280 ksi) have been attributed to stress concentration that resulted from a large grain size in the shank. Other failures in these 25 mm (1 in.) diam bolts, as well as in other similarly quenched and tempered steel bolts, were the result of cracks in untempered martensite that formed as a result of overheating during finish grinding.

Fig. 10 Uniform, unbroken grain flow around the contours of the forged head of a threaded fastener. The uniform, unbroken grain flow minimizes stress raisers and unfavorable shear planes and therefore improves fatigue strength.

Influence of the Thread-Forming Method on Bolt Fatigue Strength. The method of forming the thread is an important factor influencing the fatigue strength of bolts. Specifically, there is a marked improvement when threads are rolled rather than either cut or ground, particularly when the threads are rolled after the bolt has been heat treated (Fig. 11).

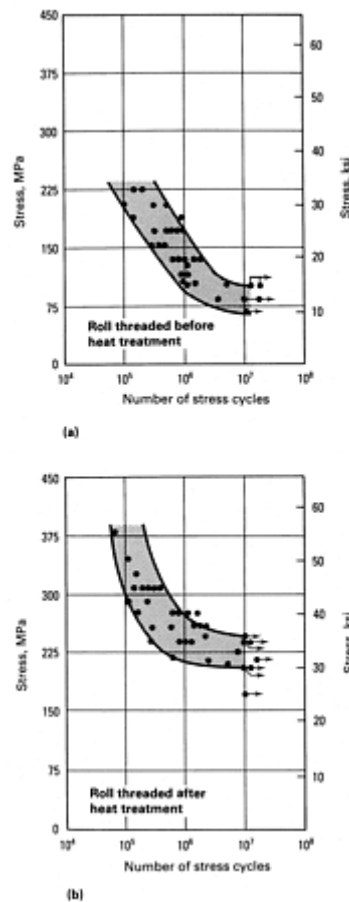

Fig. 11 Fatigue limits for roll-threaded steel bolts. (a) Four different lots of bolts that were roll threaded, then heat treated to average hardness of 22.7, 26.6, 27.6, and 32.6 HRC. (b) Five different lots that were heat treated to average hardnesses of 23.3, 27.4, 29.6, 31.7, and 33.0 HRC, then roll threaded. Bolts having higher hardnesses in each category had higher fatigue strengths.

Other factors being equal, a bolt with threads properly rolled after heat treatment--that is, free from mechanical imperfections--has a higher fatigue limit than one with cut threads. This is true for any strength category. The cold work of rolling increases the strength at the weakest section (the thread root) and imparts residual compressive stresses, similar to those imparted by shot peening. The larger and smoother root radius of the rolled thread also contributes to its superiority. Because of the fatigue life concern, all bolts and screws greater than grade 1 and less than 19 mm ($\frac{3}{4}$ in.) in diameter and 150 mm (6 in.) in length are to be roll threaded. Studs and larger bolts and screws may have the threads rolled, cut or ground.

Effect of Surface Treatment on Fatigue. Light cases, such as from carburizing or carbonitriding, are rarely recommended and should not be used for critical externally threaded fasteners, such as bolts, studs, or U-bolts. The cases are quite brittle and crack when the fasteners are tightened or bent in assembly or service. These cracks may then lead to fatigue cracking and possible fracture.

Chromium and nickel platings decrease the fatigue strength of threaded sections and should not be used except in a few applications, such as automobile bumper studs or similar fasteners that operate under conditions of low stress and require platings for appearance. Cadmium and zinc platings slightly reduce fatigue strength. Electroplated parts for high-strength applications should be treated after plating to eliminate or minimize hydrogen embrittlement (which is a strong contributor to fatigue cracking).

Installation. As noted at the beginning of this section on fatigue failures, bolt loading is a major factor in the fatigue failure of threaded fasteners. When placed into service, bolts are most likely to fail by fatigue if the assemblies involve

soft gaskets or flanges, or if the bolts are not properly aligned and tightened. Fatigue resistance is also related to clamping force. In many assemblies, a certain minimum clamping force is required to ensure both proper alignment of the bolt in relation to other components of the assembly and proper preload on the bolt. The former ensures that the bolt will not be subjected to undue eccentric loading, and the latter that the correct mean stress is established for the application. In some cases, clamping stresses that exceed the yield strength may be desirable; experiments have shown that bolts clamped beyond the yield point have better fatigue resistance than bolts clamped below the yield point.

Decreasing the bolt stiffness can also reduce cyclic stresses. Methods commonly used are reduction of the cross-sectional area of the shank to form a waisted shank and rolling the threads further up the exposed shank to increase the "spring" length.

Stress-corrosion cracking (SCC) is an intergranular fracture mechanism that sometimes occurs in highly stressed fasteners after a period of time, and it is caused by a corrosive environment in conjunction with a sustained tensile stress above a threshold value. An adverse grain orientation increases the susceptibility of some materials to stress corrosion. Consequently, SCC can be prevented by excluding the corrodent, by keeping the static tensile stress of the fastener below the critical level for the material and grain orientation involved, or by changing to a less susceptible material or material condition. Because tensile loads (even residual tensile loads) are required to produce SCC, compressive residual stresses may prevent SCC.

As with the environmentally induced cracking from hydrogen embrittlement and liquid-metal embrittlement (see the article "Embrittlement of Steels" in this Volume), the understanding of SCC is largely phenomenological, without any satisfactory mechanistic model for predicting SCC or the other forms of environmentally induced cracking. This lack of mechanistic predictability of SCC is particularly unfortunate because measurable corrosion usually does not occur before or during crack initiation or propagation. Even when corrosion does occur, it is highly localized (that is, pitting, crevice attack) and may be difficult to detect. Moreover, SCC is a complex synergistic phenomenon resulting from the combined simultaneous interaction of mechanical and chemical conditions. Pre-corrosion followed by loading in an inert environment will not result in any observable crack propagation, while simultaneous environmental exposure and application of stress will cause time-dependent subcritical crack propagation.

The susceptibility of a metal to SCC depends on the alloy and the corrodent. The National Association of Corrosion Engineers, the Materials Technology Institute of the Chemical Process Industries, and others have published tables of corrodents known to cause SCC of various metal alloy systems (Ref 2, 3, 4). This literature should be used only as a guide for screening candidate materials for further in-depth investigation, testing, and evaluation. In general, plain carbon steels are susceptible to SCC by several corrodents of economic importance, including aqueous solutions of amines, carbonates, acidified cyanides, hydroxides, nitrates, and anhydrous ammonia. Carbon steels, low-alloy steels, and H-11 tool steels with ultimate tensile strengths above 1380 MPa (200 ksi) are susceptible to SCC in a seacoast environment. Of the various bolt steels, bolts made from ISO class 12.8 have experienced failures for SCC in automotive applications (Ref 1). Stainless steels are also susceptible to SCC in some environments.

Even though the micromechanistic causes of SCC are not entirely understood, some investigators consider SCC to be related to hydrogen damage and not strictly an active-path corrosion phenomenon. Although hydrogen can be a factor in the SCC of certain alloys (see Example 1), sufficient data are not available to generalize this concept. For example, SCC can be assisted by such factors as nuclear irradiation. More information on SCC is available in *Corrosion*, Volume 13 of *ASM Handbook*.

Example 1: Hydrogen-Assisted SCC Failure of Four AISI 4137 Steel Bolts.

Figure 12 shows an example of hydrogen-assisted SCC failure of four AISI 4137 steel bolts having a hardness of 42 HRC. Although the normal service temperature (400 °C, or 750 °F) was too high for hydrogen embrittlement, the bolts were also subjected to extended shutdown periods at ambient temperatures. The corrosive environment contained trace hydrogen chloride and acetic acid vapors as well as calcium chloride if leaks occurred. The exact service life was unknown. The bolt surfaces showed extensive corrosion deposits. Cracks had initiated at both the thread roots and the fillet under the bolt head. Figure 12(b) shows a longitudinal section through the failed end of one bolt. Multiple, branched cracking was present, typical of hydrogen-assisted SCC in hardened steels. Chlorides were detected within the cracks and on the fracture surface. The failed bolts were replaced with 17-4 PH stainless steel bolts (Condition H 1150M) having a hardness of 22 HRC (Ref 5).

Fig. 12 4137 steel bolts (hardness: 42 HRC) that failed by hydrogen-assisted SCC caused by acidic chlorides from a leaking polymer solution. (a) Overall view of failed bolts. (b) Longitudinal section through one of the failed bolts in (a) showing multiple, branched hydrogen-assisted stress-corrosion cracks initiating from the thread roots. Source: Ref 5

Fabrication

Most bolts are made by cold heading. Other cold-forming methods, including cold extrusion, are used in the manufacture of threaded fasteners. Current technology is such that not only low-carbon steels but also medium-carbon and even low-alloy steels can be successfully impact extruded.

Parts having heads that are large in relation to the shank diameter can be hot headed or produced cold on a two-die, three-blow machine. Hot heading is also more practical for bolts with diameters larger than about 32 mm ($1\frac{1}{4}$ in.) because of equipment limitations and increased probability of tool failures with cold heading.

Platings and Coatings. Most carbon steel fasteners are plated or coated. Common coatings are zinc, cadmium, and phosphate and oil. Other supplementary finishes are gaining popularity, especially in critical applications. The principal reason for fastener plating or coating is corrosion resistance (see the section "Corrosion Protection" in this article), although the appearance and the installation torque-tension relationship are also improved.

Plating is the deposition of metal onto the surface of the base metal. For commercial applications, plating is achieved by electroplating, hot dipping, or mechanical application. In general, the addition of plating increases the dimensions of the fastener by two times the plating thickness and by almost four times the plating thickness in the thread dimensions. The thread assembly may be affected by the increase in fastener size due to plating.

High-strength fasteners, usually with higher carbon content, are susceptible to hydrogen embrittlement when being acid cleaned, electrocleaned, or electroplated. Hydrogen penetration into a fastener can be minimized by baking at about 190 to 200 °C (375 to 400 °F) for 3 to 24 h. For applications in which hydrogen embrittlement is a concern or for a critical application of high-strength fasteners, the mechanical application of plating should be considered.

Clamping Forces

To operate effectively and economically, threaded fasteners should be designed to be torqued near the proof stress, as dictated by the cross-sectional area of the load-carrying parts of the fastener and the desired clamping force. The actual clamping force attained in any assembly will be influenced by such factors as:

- Roughness of the mating surfaces
- Coatings, contaminants, or lubricants on the mating surfaces
- Platings or lubricants on the threads

Typically, torque values are established to result in a clamping force equal to about 75% of the proof load. For some applications, bolts are torqued beyond their proof stress with no detrimental results, provided they are permanent fasteners holding static loads.

Because it is difficult to measure bolt tension (clamping force) in production installations, torque values are used in most applications. Some critical joints in assembly-line processes are using torque-angle or torque-to-yield methods of tightening. In the torque-angle method, the bolt is torqued to a low seating torque level to mate all surfaces, then rotated a specific angle. The angle rotation has a linear relationship with extension because of the constant pitch and therefore with clamp load. In the torque-to-yield method, torque and angular rotation are monitored during installation by a microprocessor and bolt rotation continues until the relationship between the two is not linear. This point is defined as the yield point in torque tension.

The clamping forces generated at given torques are very dependent on the coefficient of friction at the threads and at the bearing face; therefore, they are highly dependent on fastener coatings. Common fastener coatings are zinc, cadmium, and phosphate and oil.

The maximum clamping force that can be effectively employed in any bolt is often limited by the compressive strength of the materials being bolted. If this value is exceeded, the bolt head or nut will be pulled into the parts being bolted, with a subsequent reduction in clamping force. The assembly then becomes loose, and the bolt is susceptible to fatigue failure. If high-tensile bolts are necessary to join low compressive strength materials, hardened washers should be used under the head of the bolt and under the nut to distribute bearing pressure more evenly and to avoid the condition described above.

The value of high clamping forces, apart from lessening the possibility of the nut loosening, is that the working stresses (against solid abutments) are always less than the clamping forces induces in a properly selected bolt. This ensures against cyclic stress and possible fatigue failure.

Steel Springs

Revised by Loren Godfrey, Associated Spring/Barnes Group, Inc.

Introduction

STEEL SPRINGS are made in many types, shapes, and sizes, ranging from delicate hairsprings for instrument meters to massive buffer springs for railroad equipment. The major portion of this article discusses those relatively small steel springs that are cold wound from wire. Relatively large, hot-wound springs are quite different from cold-wound springs and are treated in a separate section. Flat and leaf springs are also treated separately to the extent that they differ from wire springs in material and fabrication.

Wire springs are of four types: compression springs (including die springs), extension springs, torsion springs, and wire forms. Compression springs are open wound with varying space between the coils and are provided with plain, plain and ground, squared, or squared and ground ends. The spring can be cylindrical, conical, barrel, or hour glass shaped. Extension springs are normally close wound, usually with specified initial tension, and, because they are used to resist pulling forces, are provided with hook or loop ends to fit the specific application. Ends may be integral parts of the spring or specially inserted forms. Torsion springs are usually designed to work over an arbor and to resist a force that causes the spring to wind. Wire forms are made in a wide variety of shapes and sizes.

Flat springs are usually made by stamping and forming of strip material into shapes such as spring washers. However, there are other types, including motor springs (clock type), constant-force springs, and volute springs, that are wound from strip or flat wire.

Chemical composition, mechanical properties, surface quality, availability, and cost are the principal factors to be considered in selecting steel for springs. Both carbon and alloy steels are used extensively.

Steels for cold-wound springs differ from other constructional steels in four ways.

- They are cold worked more extensively
- They are higher in carbon content
- They can be furnished in the pretempered condition
- They have higher surface quality

The first three items increase the strength of the steel, and the last improves fatigue properties. For flat, cold-formed springs made from steel strip or flat wire, narrower ranges of carbon and manganese are specified than for cold-wound springs made from round or square wire.

Where special properties are required, spring wire or strip made of stainless steel, a heat-resistant alloy, or a nonferrous alloy can be substituted for the carbon or alloy steel, provided that the design of the spring is changed to compensate for the differences in properties between the materials (see the section "Design" in this article).

Table 1 lists grade, specification, chemical composition, properties, method of manufacture, and chief applications of the materials commonly used for cold-formed springs. Hot-formed carbon and alloy steel springs are discussed in this article.

Table 1 Common wire and strip materials used for cold-formed springs

Material type	Grade and specification	Nominal composition, %	Tensile properties		Torsion properties		Hardness, HRC ^(c)	Max allowable temperature, °C (°F)	Method of manufacture, chief applications, special properties
			Minimum tensile strength ^(a) , MPa (ksi)	Modulus of elasticity (<i>E</i>), GPa (psi × 10 ⁶)	Design stress, % of minimum tensile strength ^(b)	Modulus of rigidity (<i>G</i>), GPa (psi × 10 ⁶)			
Cold drawn wire									
High-carbon steel	Music wire, ASTM A 228	C 0.70-1.00, Mn 0.20-0.60	1590-2750 (230-399)	210 (30)	45	80 (11.5)	41-60	120 (250)	Drawn to high and uniform tensile strength; for high-quality springs and wire forms
	Hard drawn, ASTM A 227	C 0.45-0.85, Mn 0.30-1.30	Class I 1010-1950 (147-283) Class II 1180-2230 (171-324)	210 (30)	40	80 (11.5)	31-52	120 (250)	For average-stress applications; lower-cost springs and wire forms
	High-tensile hard drawn, ASTM A 679	C 0.65-1.00, Mn 0.20-1.30	1640-2410 (238-350)	210 (30)	45	80 (11.5)	41-60	120 (250)	For higher-quality springs and wire forms
	Oil tempered, ASTM A 229	C 0.55-0.85, Mn 0.30-1.20	Class I 1140-2020 (165-294) Class II 1320-2330 (191-324)	210 (30)	45	80 (11.5)	42-55	120 (250)	Heat treated before fabrication; for general-purpose springs
	Carbon VSQ ^(d) , ASTM A 230	C 0.60-0.75, Mn 0.60-0.90	1480-1650 (215-240)	210 (30)	45	80 (11.5)	45-49	120 (250)	Heat treated before fabrication; good surface condition and uniform tensile strength

Alloy steel	Chromium vanadium, ASTM A 231, A 232 ^(d)	C 0.48-0.53, Cr 0.80-1.10, V 0.15 min	1310-2070 (190-300)	210 (30)	45	80 (11.5)	41-55	220 (425)	Heat treated before fabrication; for shock loads and moderately elevated temperature; ASTM A 232 for valve springs
	Modified chromium vanadium VSQ ^(d) , ASTM A 878	C 0.60-0.75, Cr 0.35-0.60, V 0.10-0.25	1410-2000 (205-290)	Heat treated before fabrication; for valve springs and moderately elevated temperatures
	Chromium silicon, ASTM A 877 ^(d) , A 401	C 0.51-0.59, Cr 0.60-0.80, Si 1.20-1.60	1620-2070 (235-300)	210 (30)	45	80 (11.5)	48-55	245 (475)	Heat treated before fabrication; for shock loads and moderately elevated temperature; ASTM A 877 for valve springs
Stainless steel	Type 302(18-8), ASTM A 313	Cr 17-19, Ni 8-10	860-2240 (125-325)	190 (28)	30-40	69 (10.0)	35-45	290 (550)	General-purpose corrosion and heat resistance; magnetic in spring temper
	Type 316, ASTM A 313	Cr 16-18, Ni 10-14, Mo 2-3	760-1690 (110-245)	190 (28)	40	69 (10.0)	35-45	290 (550)	Good heat resistance; greater corrosion resistance than 302; magnetic in spring temper
	Type 631 (17-7 PH), ASTM A 313	Cr 16-18, Ni 6.50-7.75, Al 0.75-1.50	Condition CH-900 1620-2310 (235-335)	200 (29.5)	45	76 (11.0)	38-57	340 (650)	Precipitation hardened after fabrication; high strength and general-purpose corrosion resistance; magnetic in spring temper
Nonferrous alloys	Copper alloy 510 (phosphor bronze A), ASTM B 159	Cu 94-96, Sn 4.2-5.8	720-1000 (105-145)	100 (15)	40	43 (6.25)	98-104 ^(e)	90 (200)	Good corrosion resistance and electrical conductivity
	Copper alloy 170 (beryllium copper) ASTM B 197	Cu 98, Be 1.8-2.0	1030-1590 (150-230)	130 (18.5)	45	50 (7.0)	35-42	200 (400)	Can be mill hardened before fabrication; good corrosion resistance and electrical conductivity; high mechanical properties

	Monel 400, AMS 7233	Ni 66, Cu 31.5	1000-1240 (145-180)	180 (26)	40	65 (9.5)	23-32	230 (450)	Good corrosion resistance at moderately elevated temperature

(a) Minimum tensile strength varies within the given range according to wire diameter (see the applicable specification). Maximum tensile strength is generally about 200 MPa (30 ksi) above the minimum tensile strength.

(b) For helical compression or extension springs; design stress of torsion and flat springs taken as 75% of minimum tensile strength.

(c) Correlation between hardness and tensile properties of wire is approximate only and should not be used for acceptance or rejection.

(d) Valve-spring quality.

(e) HRB values.

(f) Federal specification.

Mechanical Properties

Steels of the same chemical composition may perform differently because of different mechanical and metallurgical characteristics. These properties are developed by the steel producer through cold work and heat treatment or by the spring manufacturer through heat treatment. Selection of round wire for cold-wound springs is based on minimum tensile strength for each wire size and grade (Fig. 1) and on minimum reduction in area (40% for all sizes).

Fig. 1 Minimum tensile strength of steel spring wire. VSO, valve-spring quality

Rockwell hardness and tensile strength for any grade of spring steel strip depend on thickness. The same properties in different thicknesses can be obtained by specifying different carbon contents. The relationship between thickness of spring steel strip containing 0.50 to 0.95% C and Rockwell hardness is shown in Fig. 2. The optimum hardness of a spring steel increases gradually with decreasing thickness.

Fig. 2 Effect of strip thickness on the optimum hardness of spring steel strip for high-stress use. Hardness on HRC scale may be lowered 3 to 4 points for greater toughness. Instability of ductility is sometimes encountered above 57 HRC.

The hardness scale that can be used for thin metal depends on the hardness and the thickness of the metal (see Table 3 in the article "Rockwell Hardness Testing" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*). For testing spring steel strip, which has a minimum hardness of 38 HRC, the Rockwell C scale is used for metal thicker than 0.89 mm (0.035 in.). For thickness ranges of 0.89 to 0.64 mm (0.035 to 0.025 in.), 0.64 to 0.5 mm (0.025 to 0.020 in.), and 0.5 to 0.33 mm (0.020 to 0.013 in.), the Rockwell 45N, 30N, and 15N scales are preferred. For thickness less than 0.33 mm (0.013 in.), the Vickers (diamond pyramid) scale is recommended. As the strip hardness increases, the thickness that can be safely tested decreases. It has been found that the readings obtained with the Vickers indenter are less subject to variation in industrial circumstances than those obtained with the Knoop indenter. The 500 g load Vickers test is used for spring steel strip in thicknesses as low as 0.08 mm (0.003 in.).

If readings are made using the proper hardness scale for a given thickness and hardness, they can be converted to HRC values using charts like those in the appendix to the article "Miscellaneous Hardness Tests" in *Mechanical Testing*, Volume 8 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*. Similar charts appear in ASTM A 370 and in the cold-rolled flat wire section of the Steel Products Manual of the American Iron and Steel Institute (AISI). Chart No. 60 published by Wilson Instrument Division, American Chain & Cable Company, Inc., can also be used for this conversion. For specific steel springs, hardness can be held to within 4 points on the Rockwell C scale.

Note that in Table 1 and in the section "Design" in this article, design-stress values are given as percentages of minimum tensile strength. These values apply to springs that are coiled or formed and then stress relieved, which are used in applications involving relatively few load cycles. If each spring is coiled or formed so as to allow for some set, and then deflected beyond the design requirements, higher design stresses can be used. This is discussed in the section "Residual Stresses" in this article.

As a further aid in selecting steels for springs, Table 2 lists the suitable choices for cold-wound helical springs in various combinations of size, stress, and service. Each recommendation is the most economical steel that will perform satisfactorily under the designated conditions and that is commercially available in the specific size.

Table 2 Recommended ASTM grades of carbon and alloy steel wire for cold-wound helical springs

See Table 1 for the type of wire and the composition of the ASTM grades given below.

Corrected maximum working stress ^(a)		Diameter of spring wire ^(c)					
MPa	ksi	0.31-0.51 mm (0.005-0.020 in.)	0.51-0.89 mm (0.020-0.035 in.)	0.89-3.18 mm (0.035-0.125 in.)	3.18-6.35 mm (0.125-0.250 in.)	6.35-12.70 mm (0.250-0.500 in.)	12.70-15.88 mm (0.500-0.625 in.)

- (a) Stress corrected by the Wahl factor. See the section "Wahl Correction" in this article.
- (b) To 1.37 mm (0.054 in.)
- (c) Where more than one steel is shown for an indicated range of wire diameter, the first is recommended up to the specific diameter listed in the footnote referred to; the last steel listed in any multiple choice is recommended for the remainder of the indicated wire diameter range.
- (d) To 5.26 mm (0.207 in.)
- (e) Shot peening is not necessary for statically loaded springs.
- (f) To 2.03 mm (0.080 in.)
- (g) Set removal not required in this range.
- (h) To 7.19 mm (0.283 in.).

- (i) To 14.29 mm (0.563 in.).
- (j) To 1.12 mm (0.044 in.).
- (k) To 10.32 mm (0.406 in.).
- (l) To 2.69 mm (0.105 in.).
- (m) To 4.11 mm (0.162 in.).
- (n) Yielding likely to occur beyond this limit.
- (o) To 1.83 mm (0.072 in.).
- (p) To 3.81 mm (0.150 in.).
- (q) To 11.11 mm (0.437 in.).
- (r) To 5.33 mm (0.210 in.).
- (s) To 2.29 mm (0.090 in.).
- (t) To 0.81 mm (0.032 in.).
- (u) To 0.20 mm (0.008 in.).
- (v) Shot peening is recommended for wire diameter greater than 1.57 mm (0.062 in.) and smaller where obtainable.
- (w) To 3.94 mm (0.155 in.).
- (x) To 7.77 mm (0.306 in.).
- (y) To 4.76 mm (0.187 in.).
- (z) To 2.34 mm (0.092 in.).
- ({) To 3.76 mm (0.148 in.).

(I) To 9.19 mm (0.362 in.).

(J) To 1.57 mm (0.062 in.).

(~) To 4.50 mm (0.177 in.).

(*) To 0.74 mm (0.029 in.).

(**) To 0.36 mm (0.014 in.).

Fatigue strength is another important mechanical property of steel springs. However, this property is affected by many factors, and because of this complexity, fatigue is discussed in a separate section of this article.

Flat Springs. Figure 3 illustrates the different working stresses allowable in flat and leaf springs of 1095 steel that are to be loaded in each of three different ways: statically, variably, and dynamically. (These three types of loading are dealt with separately in the selection table for cold-wound springs, Table 2). The stresses given in Fig. 3 are the maximum stresses expected in service. These data apply equally well to 1074 and 1050 steels if the stress values are lowered 10 and 20%, respectively. Except for motor or power springs and a few springs involving only moderate forming, most flat springs, because of complex forming requirements, are formed soft, then hardened and tempered.

Fig. 3 Maximum working stress for bending flat and leaf springs made of 1095 steel

For the optimum combination of properties, hypereutectoid spring steel in coil form should be held at hardening temperature for the minimum period of time. The presence of undissolved carbides indicates proper heat treatment. The extent of decarburization can be determined by microscopic examination of transverse sections or by microhardness surveys using Vickers or Knoop indentors with light loads (usually 100 g).

Power (clock) springs made from pretempered stock have a longer service life if controlled heat treatment can produce a fine, tempered martensitic structure with uniform distribution of excess carbide. If carbides are absent and the tempered

martensitic structure is relatively coarse grained, the springs will have a smaller maximum free diameter after having been tightly wound in the barrel or retainer for a long time.

A recent development for lower-stressed flat springs is a hardened, 0.04 to 0.22% plain carbon strip steel, which is blanked, formed, and used with only a low-temperature stress-relief treatment. Thickness tolerances, however, are not as close as for spring steel. This material is available in tensile strengths of 900 to 1520 MPa (130 to 220 ksi).

Characteristics of Spring Steel Grade

General Spring Quality Wire. The three types of wire used in the greatest number of applications of cold-formed springs are:

- Hard-drawn spring wire
- Oil-tempered wire
- Music wire

Hard-Drawn Spring Wire (ASTM A 227). Among the grades of steel wire used for cold-formed springs (Table 1), hard-drawn spring wire is the least costly. Its surface quality is comparatively low with regard to such imperfections as hairline seams. This wire is used in applications involving low stresses or static conditions.

Oil-tempered wire (ASTM A 229) is a general-purpose wire, although it is more susceptible to the embrittling effects of plating than hard-drawn spring wire. Its spring properties are obtained by heat treatment. Oil-tempered wire is slightly more expensive than hard-drawn wire; it is significantly superior in surface smoothness, but not necessarily in seam depth. Most cold-wound automotive springs are made of oil-tempered wire, although a small percentage are made of music wire and hard-drawn spring wire.

Music wire (ASTM A 228) is the carbon steel wire used for small springs. It is the least subject to hydrogen embrittlement by electroplating (see the section "Plating of Springs" in this article) and is comparable to valve-spring wire in surface quality.

Chromium-silicon and chromium-vanadium steel spring wire and strip are suitable for moderately elevated temperature service. The chromium-silicon steel spring wire, which has better relaxation resistance than the chromium-vanadium alloy, can be used at temperatures as high as 230 °C (45 °F). The cold-drawn spring wires of the chromium-vanadium and chromium-silicon alloys (ASTM A 231 and A 401, respectively) are heat treated before fabrication, while cold-rolled chromium-vanadium (AMS 6455) and chromium-silicon (AISI 9254) strip steels (and generally carbon strip steel as well) are heat treated after rolling and spring fabrication. The chromium-vanadium and chromium-silicon steel spring wires (ASTM A 231 and A 401) can be in either the annealed or oil-tempered condition before spring fabrication. Annealing can be performed before and after drawing, while oil tempering is performed after cold drawing.

High-tensile hard-drawn wire fills the gap where high strength is needed but where the quality of music wire is not required.

Valve-Spring Quality (VSQ) Wire. All valve-spring wires have the highest surface quality attainable in commercial production, and most manufacturers require that the wire conform to aircraft quality as defined in the AISI Steel Products Manual. Most VSQ wire producers remove the surface of the wire rod before drawing to final size. This practice improves the surface quality and eliminates decarburization.

Carbon steel spring wire is the least costly of the VSQ wires. The requirements for carbon VSQ wire in an oil-tempered condition are specified in ASTM A 230.

Chromium-vanadium steel wire of valve-spring quality (ASTM A 232) is superior to the same quality of carbon steel wire (ASTM A 230) for service at 120 °C (250 °F) and above. A modified chromium-vanadium steel of valve-spring quality is also specified in ASTM A 878. This modified chromium-vanadium wire has a smaller range of preferred diameters than ASTM A 232 and a lower minimum and maximum tensile strength than ASTM A 232 for a given wire diameter.

Chromium-silicon steel VSQ wire (ASTM A 877) can be used at temperatures as high as 230 °C (450 °F). The elevated-temperature behavior of this and other steel spring wires is discussed in the section "Effect of Temperature" in this article.

Annealed Spring Wire. Carbon steel wire of valve-spring quality, as well as chromium-vanadium and chromium-silicon steel wire of both spring and valve-spring quality, can be supplied in the annealed condition. This will permit severe forming of springs with a low spring index (ratio of mean coil diameter to wire diameter) and will also permit sharper bends in end hooks. (Although a sharp bend is never desired in any spring, it is sometimes unavoidable.)

Spring made from annealed wire can be quenched and tempered to spring hardness after they have been formed. However, without careful control of processing, such springs will have greater variations in dimensions and hardness. This method of making springs is usually used only for springs with special requirements, such as severe forming, or for small quantities, because springs made by this method may have less uniform properties than those of springs made from pretempered wire and are higher in cost. The amount of cost increase depends largely on design and required tolerances, but the cost of heat treating (which often involves fixturing expense) and handling can increase total cost by more than 100%.

Stainless Steel Spring Wire. Cold-drawn type 302 stainless steel spring wire (specified in ASTM A 313) is high in heat resistance and has good corrosion resistance. The surface quality of type 302 stainless steel spring wire occasionally varies, seriously affecting fatigue resistance. Type 316 stainless is superior in corrosion resistance to type 302, particularly against pitting in salt water, but is more costly and is not considered a standard spring wire. Type 302 is readily available and has excellent spring properties in the full-hard or spring-temper condition. It is more expensive than any of the carbon steel wires for designs requiring a diameter larger than about 0.30 mm (0.012 in.) but is less expensive than music wire for sizes under about 0.30 mm (0.012 in.). In many applications, type 302 stainless can be substituted for music wire with only slight design changes to compensate for the decrease in modulus of rigidity.

For example, a design for a helical compression spring was based on the use of 0.25 mm (0.010 in.) diam music wire. The springs were cadmium plated to resist corrosion, but they tangled badly in the plating operation because of their proportions. A redesign substituted type 302 stainless steel wire of the same diameter for the music wire. Fewer coils were required because of the lower modulus of rigidity, and the springs did not require plating for corrosion resistance. The basic cost of this small-diameter stainless wire was, at the time, 20% less than the cost of the music wire. Elimination of plating and reduction of handling resulted in a total savings of 25%.

Wire Quality

Specification requirements for the spring materials listed in Table 1 include twist, coiling, fracture, or reduction-in-area tests, in addition to dimensional limits and minimum tensile strength. Such tests ensure that the wire has the expected ductility and has not been overdrawn (which could produce internal splits or voids).

In dynamic applications, in which fatigue strength is an important factor, the performance differences of spring materials depends on surface quality when materials are of similar composition and tensile strength. Because the initiation and growth of fatigue cracks is strongly affected by surface quality, seams and surface decarburization are important factors in dynamic applications of spring quality wire and especially valve-spring quality wire. Freedom from surface imperfections is of paramount importance in some applications of highly stressed springs for shock and fatigue loading, especially where replacement of a broken spring would be difficult and much more costly than the spring itself or where spring failure could cause extensive damage to other components.

Seams are evaluated visually, often after etching with hot 50% muriatic acid. The depth of metal removed can vary from 0.006 mm ($\frac{1}{4}$ mil) to 1% of wire diameter. Examination of small-diameter etched wire requires a stereoscopic microscope, preferably of variable power so that the sizes of seams can be observed in relation to the diameter of the wire. The least expensive wires can have seams that are quite pronounced. Hard-drawn and oil-tempered wires occasionally have seams as deep as 3.5% of wire diameter, but usually not deeper than 0.25 mm (0.010 in.). On the other hand, wires of the highest quality (music wire, valve-spring) have only small surface imperfections, generally not deeper than $\frac{1}{2}$ % of wire diameter. Some grades can be obtained at moderate cost, with seam depth restricted to 1% of wire diameter.

Decarburization. There is no general numerical limit on decarburization, and phrases such as "held to a minimum consistent with commercial quality" are very elastic. It is usual for seams present during hot rolling to be partly decarburized to the full depth of the seam or slightly deeper.

For valve-spring quality, however, decarburization limits are more severe. Some manufacturers permit loss of surface carbon only if it does not drop below 0.40% for the first 0.025 mm (0.001 in.) and, within the succeeding 0.013 mm (0.0005 in.), becomes equal to the carbon content of the steel. As noted previously, most manufacturers of VSQ wire eliminate surface decarburization by removing the surface of the wire rod prior to drawing to final size.

General decarburization can be detrimental to the ability to maintain load. For hot-wound springs made directly from hot-rolled bars, it is common practice to specify a torsional modulus of 72 GPa (10×10^6 psi) instead of the 80 GPa (11.5×10^6 psi) used for small spring wires. In part, this compensates for the low strength of the surface layer. Total loss of carbon from the surface during a heat-treating process is infrequent in modern wire mill products. Partial decarburization of spring wire is often blamed for spring failures, but quench cracks and coiling-tool marks are more frequently the actual causes. In wires of valve-spring or aircraft quality, a decarburized ferritic ring around the wire circumference is a basis for rejection. The net effects of seams and decarburization are described in the section "Fatigue " in this article.

Magnetic Particle and Eddy Current Testing. Inspection for seams and other imperfections in finished springs is generally carried out by magnetic particle inspection. In its various forms, this inspection method has proved to be the most practical nondestructive method for the inspection of springs that may affect human safety or for other reasons must not fail as a result of surface imperfections. For compression and extension springs, the inspection is always concentrated selectively on the inside of the coil, which is more highly stressed than the outside and is the most frequent location of start of failure.

Valve-spring wire is often 100% eddy current tested for seams and point defects by the wire mill. The defects are painted to ensure that they are not fabricated into finished springs.

Residual Stresses

Residual stresses can increase or decrease the strength of a spring material, depending on their direction. For example, residual stresses induced by bending strengthen wire for deflection in the same direction while weakening it for deflection in the opposite direction. In practice, residual stresses are either removed by stress relieving or induced to the proper direction by cold setting and shot peening.

Compression springs, torsion springs, flat springs, and retaining rings can be stress relieved and cold set. The treatment used depends on the design and application requirements of the individual spring.

Many compression springs are preset for use at higher stress. They are then known as springs with set removed. Compression springs can be made to close solid, without permanent set and without presetting, if the shear stress is less than a specified proportion of the tensile strength of the wire in the fully compressed spring (about 45% for music wire) and if the springs are properly stress relieved. The maximum shear stress in a fully compressed preset spring is about 33% higher, or approximately 60% of the tensile strength of the wire. Therefore, presetting to a maximum stress will permit the use of up to 45% less steel than is otherwise required, a savings greater than the cost of presetting for wire larger than about 3 mm ($\frac{1}{8}$ in.) in diameter. Also, the smaller, equally strong spring requires less space.

When the calculated uncorrected stress at solid height is greater than about 60% of the tensile strength (or, for cold-set springs, greater than the proportional limit stress), the spring can be neither cold set nor compressed to its solid height without taking a permanent set. Several types of springs are in this category, where the maximum permissible deflection must be calculated and positive stops provided to avoid permanent set in service.

Compression springs, cold wound from pretempered or hard-drawn high-carbon spring wire, should always be stress relieved to remove residual stresses produced in coiling. Extension springs are usually given a stress-relieving treatment to relieve stresses induced in forming hooks or other end configurations, but such treatment should allow retention of stresses induced for initial tension.

The treatment of wire retaining rings depends on whether the loading tends to increase or decrease the relaxed diameter of the spring. Most rings contain residual stresses in tension on the inside surface. For best performance, rings that are

reduced in size in the application should not be stress relieved, while expanded rings should be. This consideration applies equally to torsion springs. It is common practice to give these springs a low-temperature heat treatment to provide dimensional stability.

Stress relieving affects the tensile strength and elastic limit, particularly for springs made from music wire and hard-drawn spring wire. The properties of both types of wire are increased by heating in the range of 230 to 260 °C (450 to 500 °F). Oil-tempered spring wire, except for the chromium-silicon grade, shows little change in either tensile strength or elastic limit after stress relieving below 315 °C (600 °F). Both properties then drop because of temper softening. Wire of chromium-silicon steel temper softens only above about 425 °C (800 °F).

The properties of spring steels are usually not improved by stress relieving for more than 30 min at temperature, except for age-hardenable alloys such as 631 (17-7 PH) stainless steel, which requires about 1 h to reach maximum strength. Typical stress-relief temperatures for steel spring wire are given in Table 3.

Table 3 Typical stress-relieving temperatures for steel spring wire

Applicable only for stress relieving after coiling and not valid for stress relieving after shot peening

Steel	Temperature ^(a)	
	°C	°F
Music wire	230-260	450-500
Hard-drawn spring wire	230-290	450-550
Oil-tempered spring wire	230-400	450-750^(b)
Valve spring wire	315-400	600-750
Cr-V spring wire	315-400	600-750
Cr-Si spring wire	425-455	800-850
Type 302 stainless	425-480	800-900

(a) Based on 30 min at temperature.

(b) Temperature is not critical and can be varied over the range to accommodate problems of distortion, growth, and variation in wire size.

(c) Based on 1 h at temperature

When springs are to be used at elevated temperatures, the stress-relieving temperatures should be near the upper limit of the range to minimize relaxation in service. Otherwise, lower temperature are better.

Plating of Springs

Steel springs are often electroplated with zinc or cadmium to protect them from corrosion and abrasion. In general, zinc has been found to give the best protection in atmospheric environments, but cadmium is better in marine and similar environments involving strong electrolytes. Electroplating increases the hazards of stress raisers and residual tensile stresses because the hydrogen released at the surface during acid or cathodic electrocleaning or during plating can cause a time-dependent brittleness, which can act as though added tensile stress had been applied and can result in sudden fracture after minutes, hours, or hundreds of hours. Unrelieved tensile stresses can result in fracture during plating. Such stresses occur most severely at the inside of small-radius bends. Parts with such bends should always be stress relieved before plating. However, because even large-index springs have been found to be cracked, general stress relief is always good practice.

Preparation for plating is also very important because hydrogen will evolve from any inorganic or organic material on the metal until the material is thoroughly covered. Such contaminants may be scarcely noticeable before plating except by their somewhat dark appearance. Thorough sandblasting or tumbling may be required to remove such layers.

Hydrogen Relief Treatment. If stress relieving has been attended to, and the springs are truly clean before plating, then the usual baking treatment of around 200 °C (400 °F) for 4 h should lessen the small amount of hydrogen absorbed and redistribute it to give blister-free springs, which will not fail.

Mechanical Plating. Another technique that solves the hydrogen problem is mechanical plating, which involves cold welding particles of zinc or other soft-metal powder to an immersion copper flash plate on the spring. While some hydrogen may be absorbed during acid dipping before plating, it does not result in a time-dependent embrittlement because the plated layer is inherently porous, even though it has a shiny appearance. The hydrogen easily diffuses through the pores within 24 h, leaving the steel ductile.

Fatigue

For those springs that are dynamically loaded, it is common practice to obtain basic mechanical data from *S-N* fatigue curves. A typical *S-N* diagram is shown in Fig. 4(a). For each cycle of fatigue testing, the minimum stress is zero and the maximum stress is represented by a point on the chart. An alternative method of presenting data on the fatigue life of springs is shown in Fig. 4(b).

Fig. 4 Fatigue lives of compression coil springs made from various steels. (a) *S-N* diagram for springs made of minimum-quality music wire 0.56 mm (0.022 in.) in diameter. Spring diameter was 5.21 mm (0.205 in.); D/d was 8.32. Minimum stress was zero. Stresses corrected by Wahl factor (see the section "Wahl Correction" in this article). (b) Life of springs used in a hydraulic transmission. They were made of oil-tempered wire (ASTM A 229) and music wire (ASTM A 228). Wire diameter was 4.75 mm (0.187 in.), outside diameter of spring was 44.45 mm (1.750 in.), with 15 active coils in each spring. The springs were fatigue tested in a fixture at a stress of 605 MPa (88 ksi), corrected by the Wahl factor.

Stress Range. In most spring applications, the load varies between initial and final positive values. For example, an automotive valve spring is compressed initially during assembly, and during operation it is further compressed cyclically each time the valve opens.

The shear-stress range (that is, the difference between the maximum and minimum of the stress cycle to which a helical steel spring may be subjected without fatigue failure) decreases gradually as the mean stress of the loading cycle increases. The allowable maximum stress increase up to the point where permanent set occurs. At this point, the maximum stress is limited by the occurrence of excessive set.

Figure 5 shows a fatigue diagram for music wire springs of various wire diameters and indexes. This is a modified Goodman diagram and shows the result of many fatigue-limit tests on a single chart. In Fig. 5, the 45° line OM represents the minimum-stress of the cycle, while the plotted points represent the fatigue limits for the respective minimum stresses used. The vertical distances between these points and the minimum-stress reference line represent the stress ranges for the music wire springs.

Spring No.	Wire diameter		Spring outside diameter		Spring index
	mm	in.	mm	in.

Fig. 5 Fatigue limits for compression coil springs made of music wire. Data are average fatigue limits from *S-N* curves for 185 unpeened springs of various wire diameters run to 10 million cycles of stress. All stresses were corrected for curvature using the Wahl correction factor. The springs were automatically coiled, with one turn squared on each end, then baked at 260 °C (500 °F) for 1 h, after which the ends were ground perpendicular to the spring axis. The test load was applied statically to each spring and a check made for set three times before fatigue testing. The springs were all tested in groups of six on the same fatigue testing machine at ten cycles per second. After testing, the unbroken springs were again checked for set and recorded. Number 4 springs, tested at 1070 MPa (155 ksi) maximum stress, had undergone about $2\frac{1}{2}\%$ set after 10 million stress cycles, but the stresses were not recalculated to take this into account. None of the other springs showed appreciable set. The tensile strengths of the wires were according to ASTM A 228.

In fatigue testing, some scatter may be expected. The width of the band in Fig. 5 may be attributed partly to the normal changes in tensile strength with changes in wire diameter. There appears to be a trend toward higher fatigue limits for the smaller wire sizes. Line UT is usually drawn so as to intersect line OM at the average ultimate shear strength of the various sizes of wire.

Modified Goodman diagrams for helical springs made of several steels are shown in Fig. 6 (music wire and 302 stainless steel wire) and Fig. 7 (hard-drawn steel spring wire, oil-tempered wire, and chromium-silicon steel wire). In all instances, the plotted stress values were corrected by the Wahl factor (see the section "Wahl Correction" in this article). The data were obtained from various sources, including controlled laboratory fatigue tests, spot tests on production lots of springs, and correlation between rotating-beam fatigue tests on wire and uni-directional-stress fatigue tests on compression and extension helical springs.

Fig. 6 Modified Goodman diagrams for steel helical springs made from music wire (a and b) and 302 stainless steel wire (c and d). The graphs on the left (a and c) plot maximum allowable stresses for 10 million cycles for a similar group of wire diameters. All stresses were corrected by the Wahl factor. See text for discussion.

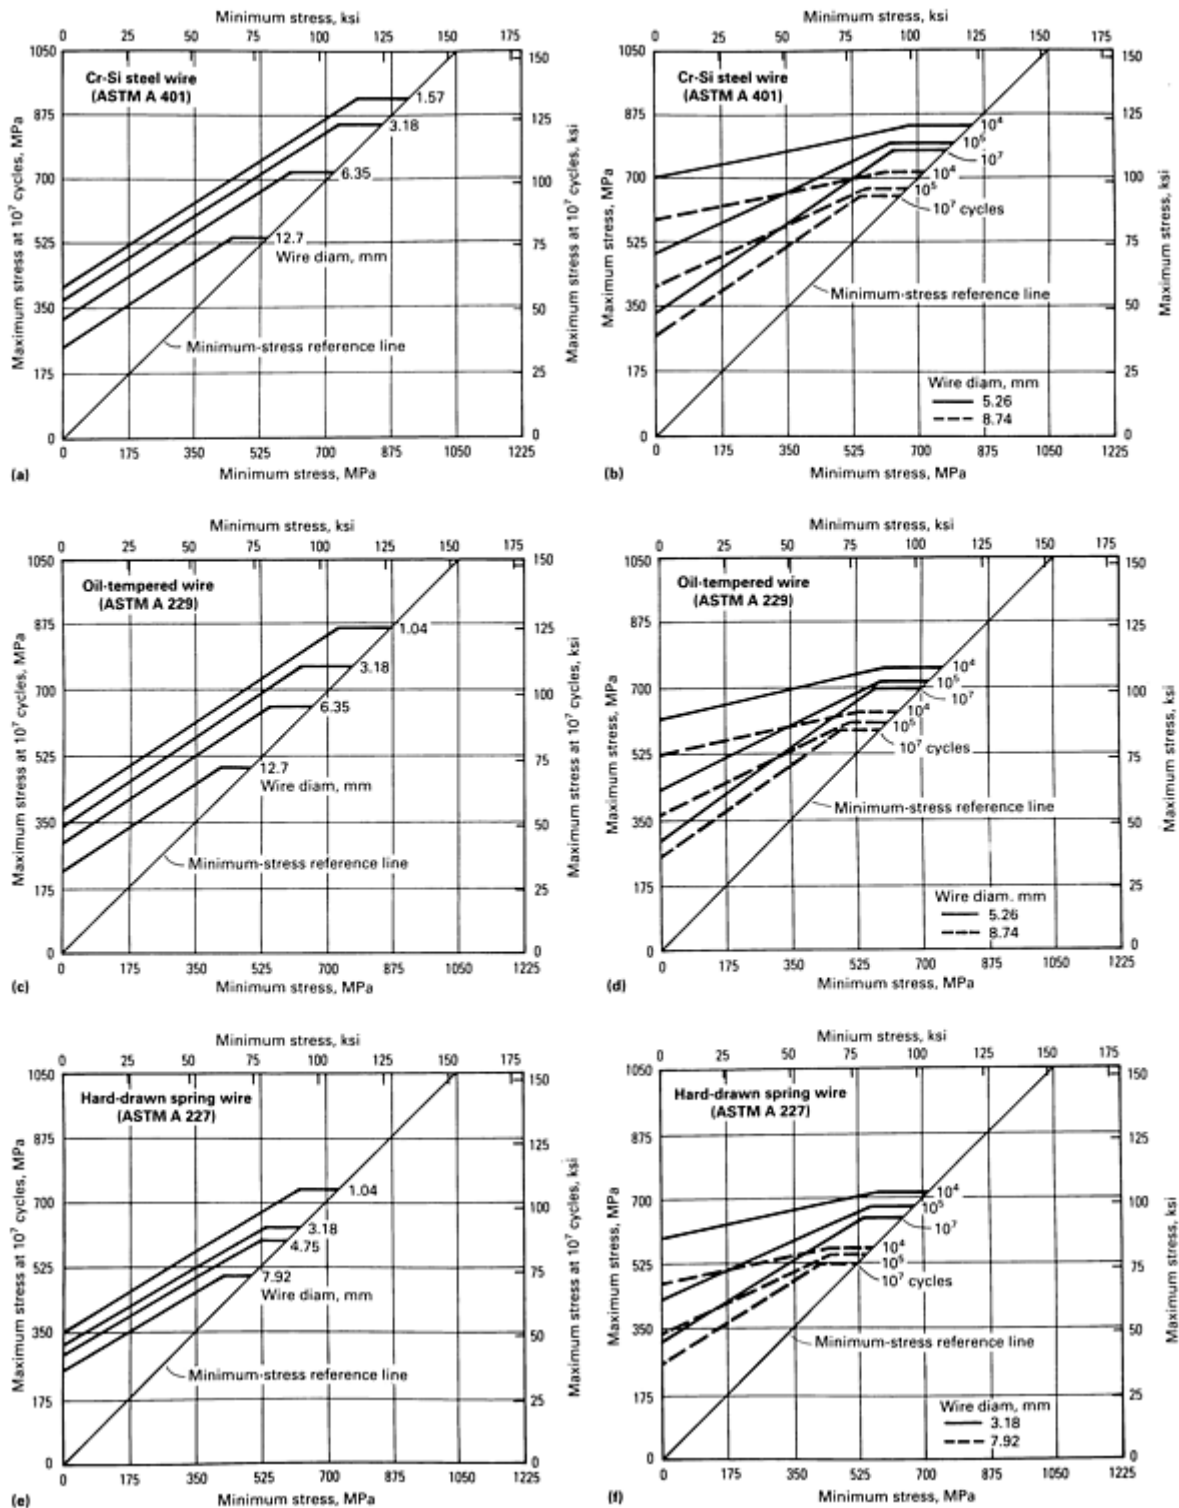

Fig. 7 Modified Goodman diagrams for steel helical springs made from chromium-silicon steel (a and b), oil-tempered wire (c and d), and hard-drawn spring wire (e and f). The graphs on the left (a, c, and e) plot maximum allowable stress for 10 million cycles for 3.18 mm (0.125 in.) diam wires and various other size wires. All stresses were corrected by the Wahl factor. See text for discussion.

The graphs on the left side of Fig. 6 and 7 plot the allowable stresses at 10 million cycles taken from $S-N$ curves for various wire size diameters. The graphs on the right side of Fig. 6 and 7 show the allowable stresses at 10,000, 10,000, and 10 million cycles for two different wire diameters. In Fig. 6 and 7, the stress range is the vertical distance between the 45° line and the lines for the several wire sizes. The allowable maximum stress increases to a point of permanent set, indicated by the horizontal sections of the lines on the diagrams. For equal wire sizes, these diagrams show that music

wire (Fig. 6a and b) is the most fatigue-resistant wire, with fatigue limits 50% greater than those of the least resistant wires (hard-drawn wires, Fig. 7e and f). This difference is largely maintained under high-stress, short-life conditions. Figures 6 and 7 represent normal quality for each grade. Because of variations in production conditions, however, quality is not constant.

Figure 8 shows the range of fatigue life for five lots of music wire, all 0.50 mm (0.020 in.) in diameter. Wire was tested on a rotating-beam machine at a maximum stress of 1170 MPa (170 ksi) and a mean stress of zero. Results were correlated with fatigue tests on torsion springs as follows. A minimum fatigue life of 50,000 cycles was required of each spring; a minimum life of 20,000 cycles for the wire in the rotating-beam machine at 1170 MPa (170 ksi) gave satisfactory correlation with the 50,000 cycle service life of springs made from the wire. Lot 5 in Fig. 8 was rejected because it failed to meet the fatigue requirement. Subsequent fatigue tests on a pilot lot of springs made from lot 5 wire confirmed the inability of these springs to meet the fatigue requirement of 50,000 cycles.

Fig. 8 Fatigue-life distribution of 0.50 mm (0.020 in.) diam music wire. Tested in a rotating-beam machine at a maximum stress of 1170 MPa (170 ksi) and a mean stress of zero

Shot peening of springs improves fatigue strength by prestressing the surface in compression. It is usually applied to wire 1.6 mm ($\frac{1}{16}$ in.) or more in diameter. The type of shot used is important; better results are obtained with carefully graded shot having no broken or angular particles. Shot size may be optimum at 10 to 20% of the wire diameter. However, for larger wire, it has been found that excessive roughening during peening with coarse shot lessens the benefits of peening, apparently by causing minute fissures. Also, peening thin material too deeply leaves little material in residual tension in the core; this negates the beneficial effect of peening, which requires internal tensile stress to balance the surface compression.

Shot peening is effective in largely overcoming the stress-raising effects of shallow pits and seams. Proper peening intensity is an important factor, but more important is the need for both the inside and outside surfaces of helical springs to be thoroughly covered. An Almen test strip necessarily receives the same exposure as the outside of the spring, but to reach the inside, the shot must pass between the coils and is thus greatly restricted. As a result, for springs with closely

spaced coils, a coverage of 400% on the outside may be required to achieve 90% coverage on the inside. Cold-wound steel springs are normally stress relieved after peening to restore the yield point. A temperature of 230 °C (450 °F) is common because higher temperatures degrade or eliminate the improvement in fatigue strength.

The extent of improvement in fatigue strength to be gained by shot peening, according to one prominent manufacturer of cold-wound springs, is shown in Fig. 9. The bending stresses apply to flat springs, power springs, and torsion springs; the torsional stresses apply to compression and extension springs.

Fig. 9 Fatigue curves for peened and unpeened steel spring wires

Effect of Temperature

The effect of elevated temperatures on the mechanical properties and performance of fabricated springs is shown in Fig. 10, 11, 12, 13, and 14. The effect is reported as amount of load loss (relaxation), which is a function of chemical composition, maximum stress, and spring processing.

Fig. 10 Relaxation curves for steel helical springs of music wire (ASTM A 228), chromium-silicon spring wire (ASTM A 401), oil-tempered spring wire (ASTM A 229), chromium-vanadium spring wire (ASTM A 231), and hard-drawn spring wire (ASTM A 227) at (a) 90 °C (200 °F) and (b) 150 °C (300 °F). Relaxation curves for the low-alloy steel spring wires (ASTM A 231 and A 401) are also plotted at (c) 200 °C (400 °F) and (d) 260 °C (500 °F). All curves represent relaxation after exposure for 72 h at indicated temperatures.

Fig. 11 Relaxation curves for steel helical springs made of (a) 302 stainless steel and (b) 631 stainless steel. The curves represent relaxation after exposure for 72 h at the indicated temperatures.

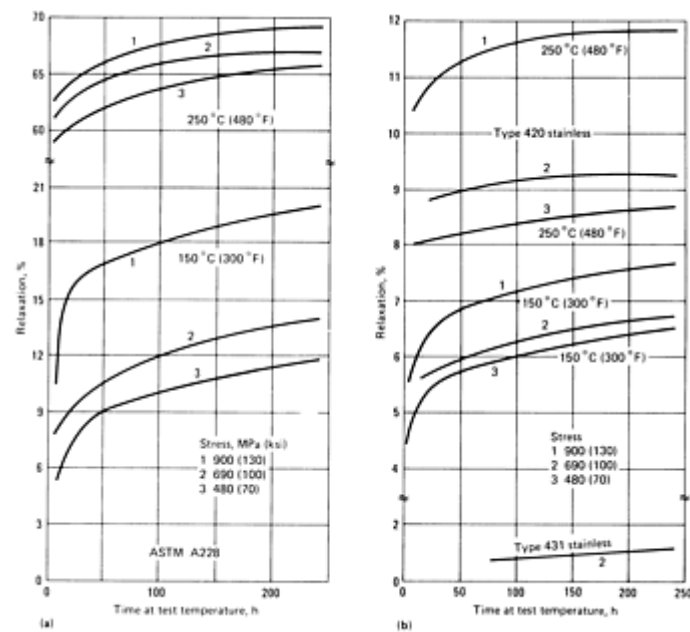

Fig. 12 Effect of time and temperature on the relaxation of ten-turn helical springs made from (a) music wire per ASTM A 228 and (b) 420 and 431 stainless steel wire. Wire diameter, 2.69 mm (0.106 in.); spring diameter, 25.4 mm (1.00 in.); free length, 76.2 mm (3.00 in.). Stresses were corrected by the Wahl factor.

Fig. 13 Relaxation of carbon steel (1070, 1095) and SAE 52100 alloy steel circular flat springs (piston rings) at elevated temperatures. Spring hardness was 35 HRC. Springs were exposed to the indicated temperatures for 3 to 4 h.

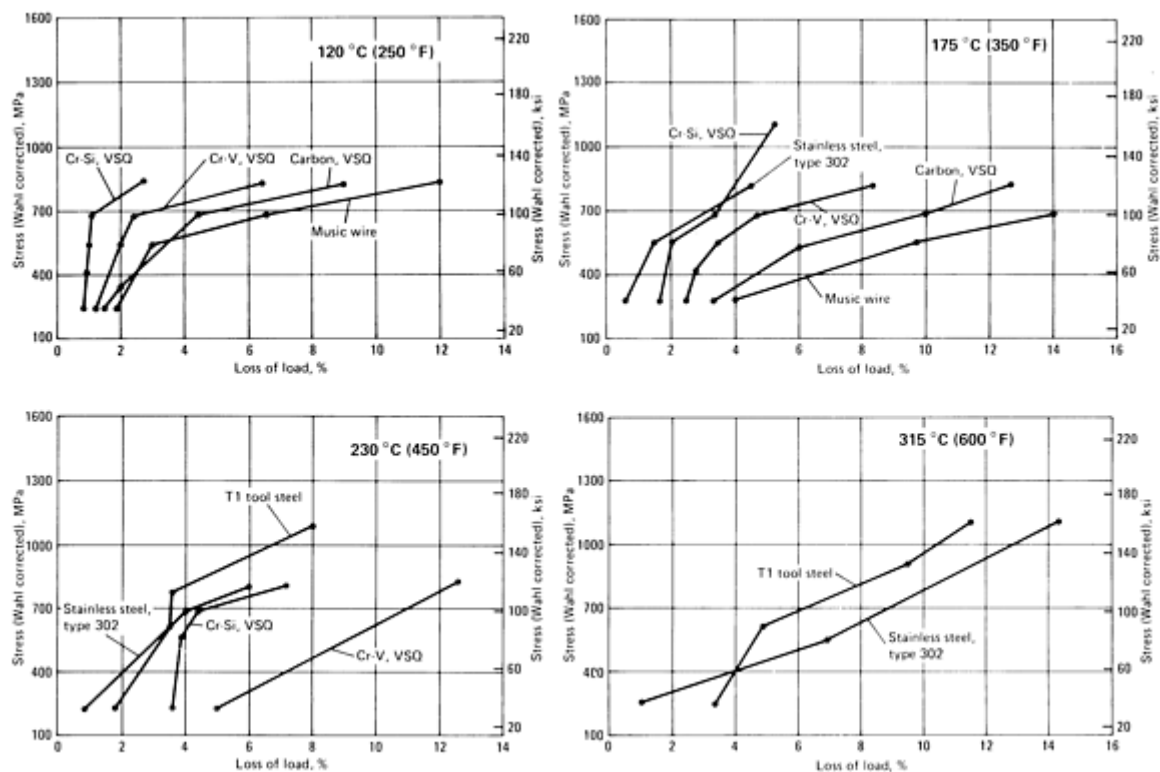

Fig. 14 Load-loss curves at various temperatures for helical compression steel springs made of music wire (ASTM A 228), VSO carbon steel spring wire (ASTM A 230), VSO chromium-vanadium steel spring wire (ASTM A 232), type 302 stainless steel spring wire (ASTM A 313), VSO chromium-silicon steel spring wire (AISI 9254), and T1 high-speed tool steel. Results are based on tests of thousands of springs. All springs were made of pretempered wire and were stress relieved after coiling; none were shot peened, and all curves are for exposure of at least 72 h at the indicated temperatures.

Figures 10 and 11 show some results from testing helical compression springs to determine the maximum relaxation at a given static working stress, temperature, and time. A specific spring height was determined for a given corrected stress. The spring was clamped at this height and placed in a convection oven for 72 h. It was removed and cooled, and the new free height was measured. Load loss was determined and amount of relaxation calculated. For example, a music wire spring designed at a corrected stress of 690 MPa (100 ksi) will relax a maximum of 3.8% when held at 90 °C (200 °F) for 72 h.

From the results shown in Fig. 10(a) and 10(b), springs made from music wire (ASTM A 228) are equal in performance to those made from oil-tempered wire (ASTM A 229) at 90 °C (200 °F) but are inferior at 150 °C (300 °F). The springs made from low-alloy steel wire such as chromium-silicon (ASTM A 401) or chromium-vanadium (ASTM A 231) provide improved relaxation resistance at elevated temperatures (Fig. 10), while the stainless steel springs (Fig. 11) exhibit further improvements in relaxation resistance. Percentage of load loss increases with shear stresses.

The effect of time and temperature on relaxation of springs is shown in Fig. 12. Rate of relaxation is greatest during the first 50 to 75 h. For longer periods of time, the rate is lower, decreasing as the logarithm of time when no structural change or softening occurs.

A significant effect of temperature on the relaxation of piston rings is indicated in Fig. 13. The rings were confined in test cylinders to maintain the outside ring diameter and were exposed to test temperature for 3 to 4 h. The load required to deflect the ring to working diameter was measured before and after each test to calculate the amount of relaxation.

Tests on thousands of springs under various loads at elevated temperatures are summarized in Fig. 14. Plain carbon spring steels of valve-spring quality are reliable at stresses up to 550 MPa (80 ksi) (corrected) and temperatures no higher than

175 °C (350 °F), in wire sizes no greater than 9.5 mm ($\frac{3}{8}$ in.). Slightly more severe applications may be successful if springs are preset at the operating temperature with loads greater than those of the application. Plain carbon spring steels of valve-spring quality should not be used above 200 °C (400 °F). To achieve an acceptable balance between relaxation and stress level, it is recommended that plain carbon steels be used at 120 °C (250 °F) or below (Table 1).

Except for high-speed steel, these tests revealed no advantage in springs heat treated after coiling compared with those at the same hardness made of pretempered wire and properly stress relieved. Deflection of a spring under load is inversely proportional to the modulus of rigidity, G , of the material. Variation with temperature is shown in Fig. 15.

Fig. 15 Effect of temperature on modulus of rigidity of spring steels

A uniform deflection under load over a range of temperatures sometimes must be maintained. The instrument spring shown in Fig. 16 required a constant modulus up to 90 °C (200 °F) and, when made of music wire, drifted 5% in service. It was replaced with a satisfactory spring made of a nickel alloy with constant modulus (Fe-42Ni-5.4Cr-2.40Ti-0.60Al-0.45Mn-0.55Si-0.06C).

Fig. 16 Helical instrument spring that required a constant modulus of rigidity up to 90 °C (200 °F)

In another example, a spring was originally fabricated from oil-tempered wire (ASTM A 229) and performed satisfactorily when tested at room temperature. However, in service it was immersed in oil that attained a temperature slightly above 90 °C (200 °F), which was high enough to cause excessive relaxation over a period of 2 to 3 h. Chromium-silicon steel spring wire (ASTM A 401) was substituted for the oil-tempered wire, and at the identical operating temperature service was satisfactory. Design data for these springs are given in Table 4.

Table 4 Comparison of two spring materials for elevated-temperature service

Grade of wire ^(a)	Condition at elastic limit			
	Load		Total deflection	
	kg	lb	mm	in.
Oil-tempered (A229)	122.7	270.5	19.3	0.76

(a) Design data (the same for both types of wire): mean diameter, 15.88 mm (0.625 in.); inside diameter, 12.12 mm (0.477 in.); wire diameter, 3.76 mm (0.148 in.); spring index, 4.22; total number of coils, 10; number of active coils, 8; spring rate, 6.36 kg/mm (356 lb/in.); working load, 5.17 kg (114 lb); deflection at working load, 7.92 mm (0.312 in.); stress at working load, 383 MPa (55.6 ksi); solid height, 37.6 mm (1.48 in.) max; free height, ~49.0 mm (1.93 in.); set removed, plain finish, variable type of load, environment of about 90 °C (200 °F)

Hot-Wound Springs

Although some hot-wound springs are made of steels that are also used for cold-wound springs, hot-wound springs are usually much larger, which results in significant metallurgical differences.

Hardenability Requirements. Steels for hot-wound springs are selected mainly on the basis of hardenability. Carbon steels with about 0.70 to 1.00% C (1070 to 1095) are suitable and widely used for statically and dynamically loaded springs in the smaller sizes. Carbon steels are also used for larger springs in the lower stress range, where some hardenability can be sacrificed safely. In most cases, alloy steels are usually required for the larger sizes because of the need for hardenability. Most specifications for hot-wound alloy steel springs require 0.50 to 0.65% C and a minimum hardness of 50 HRC at the center after oil quenching from about 815 °C (1500 °F) and before tempering. (The austenitizing temperature will vary, depending on the specific steel.)

Springs subjected to lower stress ranges may not require this high hardenability and can therefore be made of the lower-priced carbon steels. Typical minimum hardness and hardenability values are given in Table 5 for hot-wound springs used under specific conditions of stress. Here it can be seen that lower as-quenched surface hardness and lower hardenability are permitted in the lower stress ranges for both statically and variably loaded springs. These requirements gradually increase as the stress increases. After tempering, a hardness of 50 HRC is often specified for a static stress of 1240 MPa (180 ksi) or for springs dynamically loaded at 825 MPa (120 ksi).

Table 5 Typical minimum hardness and hardenability for steel used for hot-wound helical springs

As-oil-quenched, prior to tempering. Normal hardness, as-tempered, 44-49 HRC at surface

Corrected maximum solid stress		Hardness, HRC

690	100	45	35
825	120	60	50

Recommended steels for hot-wound helical springs are given in Table 6, covering variations in stress range, type of loading, and wire size. Hardenability requirements increase as required strength and/or wire diameter increases.

Table 6 Recommended steels for hot-wound helical springs

Where more than one steel is recommended for a specific set of conditions, they are arranged in the order of increasing hardenability. The first steel listed applies to the lower end of the designated wire diameter range and the last to the upper end of the range.

Corrected maximum solid stress		Diameter of spring wire (hot rolled)		
MPa	ksi	9.5-25.4 mm ($\frac{3}{8}$ -1 in.)	25.4-50.8 mm (1-2 in.)	50.8-76.2 mm (2-3 in.)

Static load (set removed, static stress up to 80% of maximum solid stress)				
825	120	1070 1095	1095	1095

Dynamic load, designed for minimum life of 2 million cycles (set removed, shot peened, 2.5% probability of failure, mean stress 515 MPa, or 75 ksi, operating stress range not over 50% of solid stress)				
690	100	1095	1095	1095
825	120	1095	51B60H 4161	4161

The strengths obtained in bars with different hardenabilities are shown in Fig. 17. The band for 1095 steel demonstrates the variation in yield strength that results from variations in the thickness of the bar and the severity of quenching and from limited hardenability. Smaller bars, as well as those quenched more rapidly from the austenitizing temperature, follow the top of the band, while larger bars and those quenched less drastically fall in the lower half of the band. For

example, a 13 mm ($\frac{1}{2}$ in.) round bar quenched in 5% caustic solution will have maximum properties, and a 50 mm (2 in.) round bar quenched in still oil will have yield strength near the minimum shown. The scatter for alloy steels in Fig. 17 is much narrower because the points only represent steels with sufficient hardenability to have a martensitic structure throughout the bar section, as-quenched.

Fig. 17 Relationship between surface hardness and yield strength of steel bars after tempering. Alloy steels were martensitic throughout the section, as-quenched; 1095 bars were 12.7 to 50.8 mm ($\frac{1}{2}$ to 2 in.) in diameter.

The distribution of hardness test results at surface and center, as-quenched and as-tempered, is shown in Fig. 18 for a multiplicity of heats of 1095 steel and five alloy steels commonly used for hot-wound springs. The results of testing specimens 300 mm (12 in.) long correlate with those of testing production springs. For the alloy steels, a minimum of 50% martensite at the center of the quenched section was specified. Table 7 lists steels that meet hardenability requirements for torsion bar springs with section thicknesses from 29.21 to 57.15 mm (1.150 to 2.250 in.).

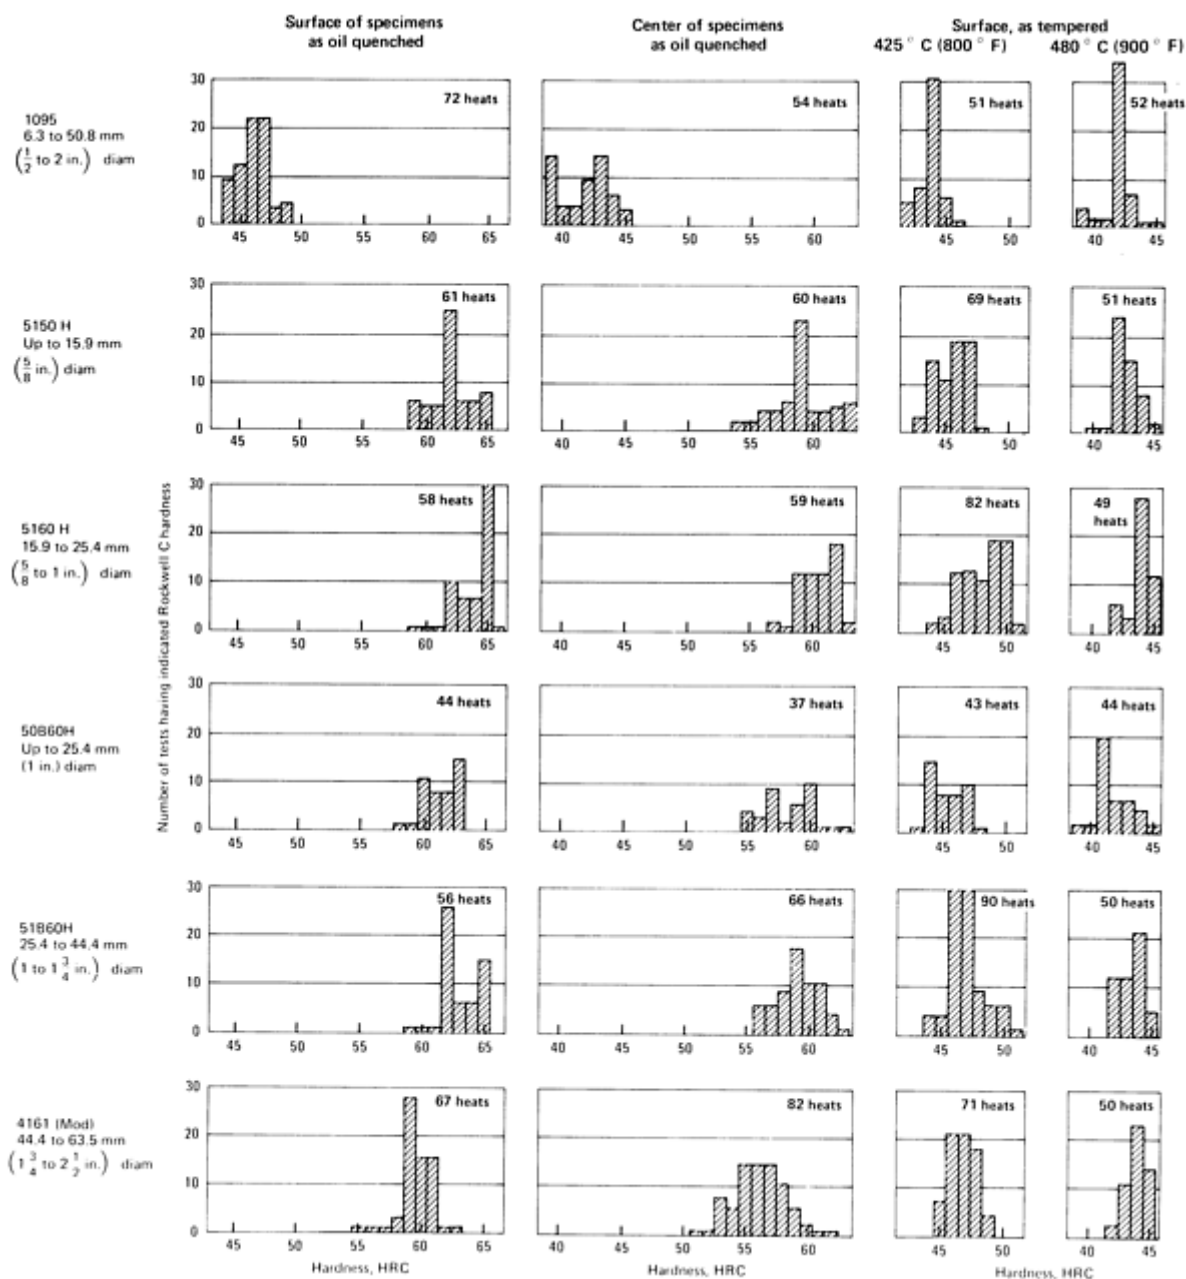

Fig. 18 Hardness distribution for steels for hot-wound helical springs. Alloy steels were oil quenched from 845 °C (1550 °F); 1095 was oil quenched from 885 °C (1625 °F). Data were obtained from hot-rolled, heat-treated laboratory test coupons, 305 mm (12 in.) long. Specimens were sectioned from the center of the coupons after heat treatment. These results on bars correlate with those on production springs. For the alloy steels, a minimum of 50% martensite at the center of the quenched section was specified.

Table 7 Steels with sufficient hardenability for torsion bar springs

Thickness of section		Minimum hardenability required	Steel
mm	in.		
29.21	1.150	J50 at 8	8650H, 5152H

33.91	1.335	J50 at 9	8655H, 50B60H
36.32	1.430	J50 at 8 $\frac{1}{2}$	50B60H
39.88	1.570	J50 at 10	51B60H
46.23	1.820	J50 at 11	8660H
48.26	1.900	J50 at 14	4150H
57.15	2.250	J50 at 22	9850H

Surface Quality. Hot-wound springs fabricated from bars of large diameter will normally show much deeper surface decarburization, in the range from 0.13 to 0.38 mm (0.005 to 0.015 in.), unless special material preparation and processing techniques are used. Although decarburization is not desirable, in some design situations the use of the favorable residual stress pattern due to shallow hardening can reduce the negative effects of decarburization on fatigue performance (Table 8). The detrimental effects of decarburization are less noticeable on hot-wound than on cold-wound springs because other weaknesses, such as the surface imperfections and irregularities typical of a hot-rolled surface, create additional focal points for fatigue cracks.

Table 8 Properties of shallow-hardened and through-hardened hot-wound (wound from bar 32 mm, or 1 $\frac{1}{4}$ in., in diameter) helical compression springs

Heat treatment	Hardness, HRC Distance below surface				Fatigue tests ^(a) Millions of cycles to failure		
	1.6 mm ($\frac{1}{16}$ in.)	3.2 mm ($\frac{1}{8}$ in.)	6.35 mm ($\frac{1}{4}$ in.)	Center	High	Low	Average
1045 steel, decarburized 0.38 mm (0.015 in.)							
As-quenched	60	50	45	30
Tempered	54.5	49	37.5	25	1.28	0.46	0.772
8655H, steel decarburized 0.03 mm (0.001 in.)							
As-quenched	60	60	60	60

(a) 485 MPa (70 ksi) stress range (corrected), 415 MPa (60 ksi) mean stress (corrected); eight springs tested in each group

Specifications for hot-wound springs and torsion bar springs usually include maximum seam depth. For example, the specifications used by a manufacturer of railway equipment allow seams with a maximum depth of 0.025 mm (0.001 in.) per 1.6 mm ($\frac{1}{16}$ in.) of wire diameter up to 0.41 mm (0.016 in.) for any bar size above 25 mm (1 in.). Another manufacturer allows seam depths of 0.41 mm (0.016 in.) for bars 25 mm (1 in.) in diameter, 0.81 mm (0.032 in.) for bars 25 to 44 mm (1.00 to 1.75 in.) in diameter, and 1.22 mm (0.048 in.) for bars 44 to 63.5 mm (1.75 to 2.50 in.) in diameter.

Design Stress. It should be noted that some organizations specify a much more conservative approach to stress than that presented in Table 6. The Spring Manufacturers Institute has adopted a chart from the Manufacturers Standardization Society of the Valve and Fittings Industry, for essentially static service, that calls for an admittedly uncorrected stress for alloy steel of 760 MPa (110 ksi) for a bar diameter of 13 mm ($\frac{1}{2}$ in.), reducing to 590 MPa (86 ksi) for a bar diameter of 92 mm ($3\frac{1}{4}$ in.). Their curve for 1095 steel is roughly 140 MPa (20 ksi) lower.

The desirability of conservative design in cyclical service is illustrated in Fig. 19, in which the minimum stress used was low. Such data on springs hot wound from bars with as-rolled surfaces are limited, and interpretation is therefore difficult. The value of peening, however, is made quite apparent. Surface imperfections can be removed by grinding, and this is normal practice, where the increased cost can be borne, in order to increase reliability at higher stresses.

Fig. 19 Effect of peening on the probability of fatigue failure of hot-wound steel springs. Top: 95% probability of failure. Middle: 50% probability of failure. Bottom: 5% probability of failure. Springs were made from 16 to 27 mm ($\frac{5}{8}$ to 1 $\frac{1}{16}$ in.) diam 8650 and 8660 hot-rolled steel and heat treated to between 429 and 444 HB. Springs were shot peened to an average arc height of 0.2 mm (0.008 in.) on the type C Almen strip at 90% visual coverage.

With all of the limitations discussed above, there can be both cost and reliability advantages in using 1095 steel at low stresses. For example, railroad freight car springs, which are subject to severe corrosion pitting, are made of 1095 steel and designed for very low stress, and very little difficulty is encountered.

Costs

The relative costs of various spring steels in the form of round wire are given in Fig. 20. Base price may be outweighed by other costs, as indicated in Table 9, which lists possible extras for two alloy spring steels of about the same base price. Also, base price and other costs will vary somewhat with time.

Fig. 20 Relative cost of spring steel wire

The amount of material in a spring can be minimized by designing for the highest safe stress level. From the equation for volume of material:

$$V = E \left(\frac{4G}{S^2} \right) \quad (\text{Eq 1})$$

in which V is the volume of material in the spring (in cubic inches), E is the spring energy (in inch-pounds), G is the torsion modulus of elasticity (in pounds per square inch), and S is the stress (in pounds per square inch). A reduction of 5% in stress level increases required volume of material by 11%.

Cost of Springs. Tolerances are often the most important factors in spring cost and should be selected with cost in mind. Tolerances superimposed on tolerances are especially costly. For example, if a free-length tolerance were specified in addition to load tolerances at each of two deflections, the cost of manufacturing the spring could be much higher than if free-length tolerance were unspecified or indicated as a reference dimension. Important dimensions can sometimes be held to close tolerances at no additional cost of allowing wider tolerances elsewhere. Springs are resilient structures, and the tight tolerances held by the machining industry are not applicable. Spring diameter tolerances can often be held to within ± 1 to 3%, while tolerances on load generally vary from ± 5 to $\pm 15\%$.

Design

All spring design is based on Hooke's Law: When a material is loaded within its elastic limit, the resulting strain in the material is directly proportional to the stress produced by the load. For springs, this means that the amount of deflection is proportional to the load or other force producing it.

Charts and formulas are available to aid in the design of springs. Charts that recommend categorically a design stress for a given spring steel can be reliable guides for springs used in static service only, unless otherwise qualified. Charts of any sort are of value only when it is known to which wire size(s) they apply, whether the data are for springs with or without presetting and with or without shot peening and whether the cited nominal stresses include a correction factor or a safety factor. The operating environment can have a pronounced effect on spring performance and is an important factor to consider in evaluating design data and in the material selection process.

The spring-design formulas given in Table 10 are valid for extension and compression springs of round and square wire below the stress at which yielding begins. For rectangular wire, the numerical coefficients vary with the ratio of width to thickness. Detailed information on these calculations is given in the SAE Handbook, Supplement J795 on Spring Design, and in the Spring Manufacturers Institute Handbook on Spring Design. Much of the labor of computation in design can be eliminated by the use of commercially available spring design software.

Table 10 Design formulas for helical extension and compression springs

Round wire	Square wire
Stress for statically loaded springs (psi)	
$S = \frac{2.55PD}{d^3}$	$S = \frac{2.4PD}{t^3}$
$S = \frac{FGd}{\pi D^2 N}$	$S = \frac{FGt}{2.32D^2 N}$
Stress for round wire corrected by the Wahl factor (Fig. 21) (psi)	
$S_K = \frac{2.55PD}{d^3} \left[\frac{4C-1}{4C-4} + \frac{0.615}{C} \right]$	
Stress for square wire corrected by Wahl factor (Fig. 21) (psi)	
$S_K = \frac{2.4PD}{t^3} \left[1 + \frac{1.2}{C} + \frac{0.56}{C^2} + \frac{0.50}{C^3} \right]$	
Wire size for given load and stress (in.)	
$d^3 = \frac{2.55PD}{S}$	$t^3 = \frac{2.4PD}{S}$
Deflection of the spring under load (in.)	
$F = \frac{8PD^3 N}{Gd^4}$	$F = \frac{5.58PD^3 N}{Gt^4}$
Spring loading at a given deflection (lbf)	
$P = \frac{FGd^4}{8D^3 N}$	$P = \frac{FGt^4}{5.58D^3 N}$
$P = \frac{Sd^3}{2.55D}$	$P = \frac{St^3}{2.4D}$
<p>Note: S is the nominal shear stress (in pounds per square inch); P is the spring load or force (in pounds); D is the mean diameter of the spring (in inches) (outside diameter of the spring minus the wire diameter); d is the diameter of the wire (in inches); t is the thickness of the square wire before coiling (in inches); F is the deflection (in inches) under load P; G is the modulus of elasticity in shear (modulus of rigidity), equal to 11.5×10^6 psi for ordinary steels and 10×10^6 psi for stainless steel near room temperature; N is the number of active coils; C is the spring index, D/d; and K is the Wahl correction factor.</p>	

Note: S is the nominal shear stress (in pounds per square inch); P is the spring load or force (in pounds); D is the mean diameter of the spring (in inches) (outside diameter of the spring minus the wire diameter); d is the diameter of the wire (in inches); t is the thickness of the square wire before coiling (in inches); F is the deflection (in inches) under load P ; G is the modulus of elasticity in shear (modulus of rigidity), equal to 11.5×10^6 psi for ordinary steels and 10×10^6 psi for stainless steel near room temperature; N is the number of active coils; C is the spring index, D/d ; and K is the Wahl correction factor.

Wahl Correction. In a straight torsion bar spring of circular section, twisting produces a shear stress uniform at every point on the surface. However, in a helical spring coiled from round wire, the stress at the inside of the coil is higher.

The first formulas for stress in helical springs shown in Table 10 do not include additional stresses that exist due to curvature and direct shear. The magnitude of these stresses varies with the amount of curvature and resultant shift in the neutral axis. A set of formulas developed by A. M. Wahl, involving a correction factor known as the Wahl factor, takes into account these two effects (Fig. 21).

Fig. 21 Wahl correction factors for helical compression or extension springs. Spring index, C , is the mean diameter of the spring, D , divided by the diameter of the wire, d . When square wire, or rectangular wire coiled on the flat side, is used, the thickness of the wire, t , is substituted for d . When rectangular wire is coiled on edge, the width, b , is substituted for d . Source: Ref 2

Table 11 shows a typical comparison between uncorrected and corrected stresses for two spring indexes and five grades of spring wire. The values in Table 11 indicate that the stress in the spring is higher because of the shift in the neutral axis at the lower index. Therefore, in the first line, if the elastic limit is less than 1080 MPa (157 ksi), the spring will take a permanent set.

Table 11 Effect of spring index on calculated spring working stress

Steel wire	Spring index	Wahl correction factor	Calculated spring working stress			
			Uncorrected		Corrected	
			MPa	ksi	MPa	ksi
Music	4.60	1.33	814	118	1082	157
	8.38	1.16	820	119	951	138

Hard drawn spring	4.60	1.33	634	92	841	122
	8.50	1.16	641	93	745	108
Oil-tempered spring	4.75	1.32	814	118	1075	156
	8.68	1.15	779	113	896	130
Chromium-vanadium spring	4.75	1.32	869	126	1145	166
	8.65	1.15	814	118	938	136
Chromium-silicon spring	4.75	1.32	1020	148	1344	195
	8.26	1.16	1076	156	1248	181

For springs with an index greater than 12, the Wahl correction is small; however, correction is needed for all springs subject to cyclic conditions.

Stress Range. Safe maximum stresses for a minimum of 10 million cycles of stress will generally be lower than the fatigue limits shown in Goodman diagrams (Fig. 5, 6, 7) because of variations in the wire (especially with regard to surface condition) and variations in the spring, manufacturing process, and application. Commercial tolerances on spring wire will also affect the selection of allowable stress for a production spring. For example, the 0.013 mm (0.0005 in.) tolerance on 0.81 mm (0.032 in.) diam music wire gives rise to a stress variation of $4\frac{1}{2}\%$. In addition, stresses vary proportionately with load tolerance. Tolerances on number of coils, squareness, and spring diameter also permit stresses different from those calculated. For these reasons, stresses near the upper fatigue limits may be unsafe for some applications.

Life. Unless required, it is wasteful to design a spring for infinite life. A fatigue curve or *S-N* diagram provides approximations of allowable stresses for designing to a desired life. For reliable operation, springs made of hard-drawn or oil-tempered wire, which may contain seams or scratches as deep as 3.5% of wire diameter or 0.25 mm (0.010 in.), should be limited to static applications or subjected to less than 10,000 loadings.

Ordinance springs typify long-stroke springs that have limited space and life requirements and that are subjected to shock loads. Stranded-wire springs have sometimes been used because of damping or design considerations. However, these springs are costly and chafe between coils. The stress level, stress range, and life (until set becomes excessive) of some springs used at high stresses, including some stranded-wire springs, are listed in Table 12. The life of these springs is not entirely dependent on maximum operating stress and stress range, but is also affected by the shock loading that is exerted. However, a fracture in one strand does not significantly affect the functioning of such a spring, which may develop several distributed breaks before becoming seriously impaired.

Table 12 Performance of highly stressed, shock-loaded music wire springs

Maximum stress		Stress range		Wire diameter		Spring index ^(a) , <i>D/d</i>	Cycles to excessive set
MPa	ksi	MPa	ksi	mm	in.		

1103	160	862	125	2.29 ^(b)	0.090 ^(b)	3.9	2000
965	140	689	100	2.49	0.098	6.8	4000
1082	157	696	101	0.94 ^(c)	0.037 ^(c)	3.4	5000

Compression Springs

The usual types of ends for compression springs are shown in Fig. 22, in order of increasing cost. An additional increase in the cost of grinding may be anticipated with close tolerances of squareness and length.

Fig. 22 Types of ends for compression springs. Cost increases from (a) to (d).

When springs are designed to work at maximum stress, allowance should be made for the effect on stress of the specified type of end. For example, in a compression spring with squared, or squared and ground, ends, the number of active coils will vary slightly throughout the deflection of the spring, and this results in spring rate and stress different from those originally calculated. This is especially important in springs having fewer than seven coils, because changes in the number of active coils result in high percentage changes in stress. The number of active coils changes because part of the active coil adjacent to the squared end closes down solid and becomes inactive as the spring approaches the fully compressed condition. In designs where this is objectionable, loads at two compressed lengths should be specified on the manufacturing print in order to ensure loads, rates, and stresses no higher than those calculated. Controlling loads in this way also controls the number of active coils.

For springs that will be operated at high stresses, tolerances that do not increase calculated stresses should be liberal so that tolerances on other dimensions that might increase stresses may be held closely. Therefore, if the number of coils must be held closely in order to keep spring stresses in control, tolerance on free length with ends ground should be large.

Active Coils. The number of active coils equals the total number of coils less those that are inactive at each end. For plain, unground ends the number of inactive coils depends on the length of contact between the end coils and the mating part. The number of active coils in a spring with plain, ground ends would approximately equal the number of turns of the wire untouched by grinding. One inactive coil on each end should be allowed in springs with squared ends or squared and ground ends. For springs of fewer than seven coils, this rule should be applied with care; in some springs, the degree of squareness should be considered.

Solid heights for the types of ends shown in Fig. 22(a) and (b) are computed by multiplying the wire diameter by the total number of coils plus one. Solid height for the type of end in Fig. 22(c) equals wire diameter times total number of coils plus one-half the wire diameter, if grinding at each end removes at least one-quarter of the wire thickness. For the end shown in Fig. 22(d), solid height is equal to the wire diameter times the total number of coils. A spring should be designed so that the coils do not touch or clash in service, because such contact will induce wear, fretting corrosion, and noise. The maximum solid height, specified primarily for inspection, should be determined after consideration of clearances and of tolerances on wire size to allow spring manufacturers to meet economically the requirements established for solid height.

Wire that is square or rectangular before coiling will upset at the inside of the coil and become trapezoidal in section during coiling. This limits deflection per coil because solid height is predicated on wire thickness at the inside of the coil. An approximate formula for the upset thickness, t_1 , at the inside compared to the original thickness, t , of the rectangular or square wire is:

$$t_l = t \left(1 + \frac{k}{c} \right) \quad (\text{Eq 2})$$

where $c = (D_o + D_i)/(D_o - D_i)$; D_o is the outside diameter of the spring; D_i is the inside diameter of the spring; and k is 0.3 for cold-wound springs and 0.4 for hot-wound springs and annealed materials. With wire that is keystone shaped before coiling, this difficulty is not encountered, but such wire is costly and is not readily available, particularly in small lots.

Effect of Modulus Change. A change in the value of G (modulus of rigidity) resulting from a change in material must be compensated for by a change in wire diameter, mean diameter, or number of active coils. If springs made from different steels must have precisely the same spring rate, the number of active coils, the wire diameter, or the mean diameter must differ. A typical example follows:

Parameter	Music wire	Type 302
Wire diameter, mm (in.)	0.25 (0.010)	0.25 (0.010)
Coil diameter, mm (in.)	5 (0.20)	5 (0.20)
Number of coils	10	8.5
Spring rate, N/cm (lb/in.)	0.313 (0.179)	0.313 (0.179)

Extension Springs

Extension springs are usually designed with some initial tension at the discretion of the spring maker. Occasionally, the pitch or space between coils is specified, or the spring must be close wound with no initial tension. When initial tension is specified, it is specified as a load with a tolerance of approximately $\pm 15\%$. In making stress calculations, initial tension is included in the load, P , and if P is measured, initial tension is included in the measurement obtained.

The necessity for fastening extension springs to some other part may require secondary operations or costly fasteners. End hooks with sharp bends may have stress concentrations that increase stresses by a factor of two or three. There are many common designs for end hooks.

End Hooks. Stresses in end hooks are combinations of torsional and bending stresses. Bending stresses diminish toward the body of the spring, where torsional stresses prevail. There is a region where both tensile and torsional stresses are present and are difficult to compute accurately. If the last coil of the spring adjacent to the end hook is reduced in diameter, the stress in the last coil and the end hook will be lower than that in the other coils.

The bending stresses in an end hook may be calculated from:

$$S_b = \frac{32PR}{pd^3} \left(\frac{r_c}{r_i} \right) \quad (\text{Eq 3})$$

where PR is the bending moment (load times moment arm from centerline of load application to centerline of wire), d is the diameter of the wire, r_c is the radius of the sharp bend measured to centerline of wire, and r_i is the inside radius of the sharp bend. The ratio r_c/r_i is an approximate evaluation of the stress-concentrating effect of the configuration these radii describe. The ratio indicates the destructive effect of a small radius, r_i . The smaller this radius, the higher the stress at the bend, other values being the same.

Because of the possibilities for overextension and the stress concentrations in the ends, allowable stresses are more likely to be exceeded in extension springs than in compression springs. Therefore, allowable stresses that are 20% lower than those for compression springs are sometimes recommended for extension springs. However, when stresses in the ends are accurately known and the stroke of the spring is controlled in design of the spring or of the associated parts, the same values for allowable stresses can be used for extension springs as for compression springs that have not been preset, provided the initial tension is relatively low.

Leaf Springs*

Leaf springs, like all other springs, serve to absorb and store energy and then to release it. During this energy cycle, the stress in the spring must not exceed a certain maximum in order to avoid settling or premature failure. This consideration limits the amount of energy that can be stored in any spring.

In this regard, leaf springs are somewhat less efficient than helical springs in terms of energy storage per unit mass of material, but they are widely used in automotive applications because they may also function as structural members. Table 13 lists values of energy that may be stored in the active parts of leaf springs designed for maximum stress of 1100 MPa (160 ksi). If consideration of the inactive part of the spring required for axle anchorage, spring eyes, and so on, is included, the energy per pound of the total spring weight will be less than shown. For comparison, the stored energy in the active material of a helical spring made of round wire is 510 J/kg (2050 in. · lbf/lb) at 1100 MPa (160 ksi) and for a torsion bar or round cross section is 390 J/kg (1570 in. · lbf/lb) at 965 MPa (140 ksi). This comparison shows that a leaf spring is inherently heavier than other types of springs. Balancing this weight disadvantage is the fact that leaf springs can also be used as attaching linkage or structural members. In order to be economically competitive, leaf springs must therefore be so designed that this advantage is fully utilized.

Table 13 Energy stored by steel leaf springs

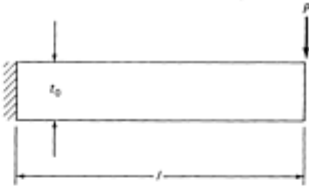

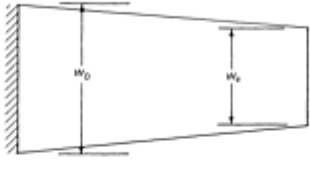

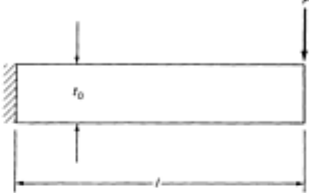

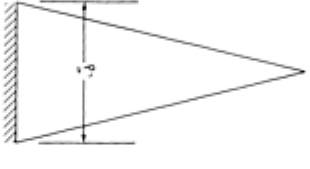

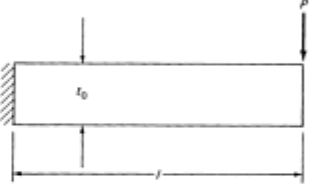

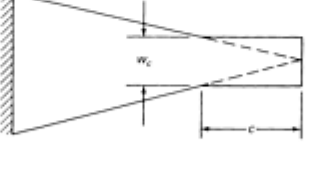

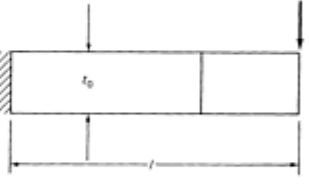

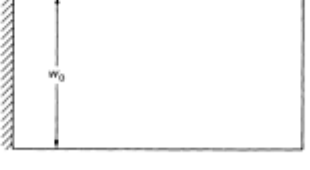

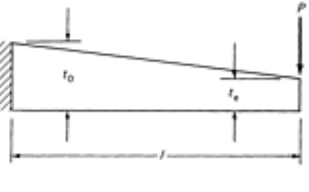

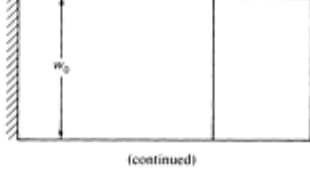

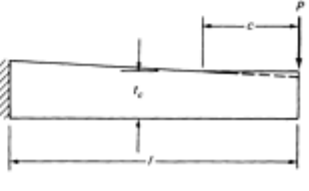

Springs designed for maximum stress of 1100 MPa (160 ksi)

Leaf type ^(a)	Spring design	Energy per unit mass of spring	
		J/kg	in. · lbf/lb
F-1	Single leaf	43	173
	Multileaf, with all leaves full length	43	173
F-2	Multileaf, with properly stepped leaves	95	380
T-2	Single leaf	106	426
T-1	Single leaf	109	438
P-2	Single leaf	122	488

(a) See Tables 14 for descriptions of leaf types

A leaf spring can be constructed of a single leaf, of several leaves of equal (full) length, or of several leaves of decreasing (stepped) lengths. The various types of leaves used in single-leaf springs are described in Tables 14. Of course, flat-profile, or type F, leaves can be used to construct multileaf springs. A leaf spring made entirely of full-length leaves of constant thickness (see type F-1) is much heavier and less efficient than a leaf spring made of properly stepped leaves (see type F-2) or a single-leaf spring (see types F-4, P-2, T-1, and T-2).

Table 14 Types of leaf springs

With flat profile: "F" types		
<p>F-1: rectangular cantilever. Constant in thickness (t_0) and in width (w_0). Under load (P), the stress is greatest at line of encasement and decreases at a constant rate to zero at line of load application. The elastic curve in bending (from an initially flat spring) has its smallest radius at line of encasement; that is, the rate of change of curvature is greatest at this line. This design is inefficient.</p>		
<p>F-2: trapezoidal cantilever. Constant in thickness (t_0). Width decreases at a constant rate from w_0 at line of encasement to a specified dimension (w_c) at line of load application. Under load (P), the stress is greatest at line of encasement. This design is more efficient than type F-1.</p>		
<p>F-3: triangular cantilever. Constant in thickness (t_0). Width decreases at a constant rate from w_0 at line of encasement to zero at point of load application. Under load (P), the stress is constant throughout the length; the elastic curve in bending is circular; that is, the rate of change of curvature is constant throughout the length. Although this design is highly efficient, it is impractical, because no material is provided for load application.</p>		
<p>F-4: modified triangular cantilever. Same as type F-3 except for an end portion of length c with constant cross section ($t_0 \times w_c$) to facilitate load application. This design is slightly less efficient than type F-3.</p>		
With tapered profile: "T" types		
<p>T-1: tapered cantilever. Constant in width (w_0). Thickness decreases at a constant rate from t_0 at line of encasement to a specified dimension (t_c) at line of load application. Under load (P), the stress is greatest at line of encasement when the t_0/t_c ratio is 0.50 or more. When the t_0/t_c ratio is less (between 0.49 and 0.24), a higher degree of efficiency is obtained, with the line of peak stress some distance away from the line of encasement. The highest efficiency (approaching but not equaling that of the triangular F-3 and of the parabolic P-1 cantilevers) occurs when t_0/t_c equals 0.357, with the peak stress (8.9% greater than at encasement) located at a distance from the line of encasement equal to 44.5% of the cantilever length (l).</p>		
<p>T-2: modified tapered cantilever. Same as type T-1 except for an end portion of length c with constant cross section ($t_c \times w_0$) for material strength required for eye or load-bearing area. This design is slightly less efficient than type T-1.</p>		

(continued)

The maximum permissible leaf thickness for a given deflection is proportional to the square of the spring length. By choosing too short a length, the designer often makes it impractical for the spring maker to build a satisfactory spring, although the requirements for normal load, deflection, and stress can be fulfilled.

When a stepped spring is made of type F-2 leaves, its length should be chosen so that the spring will have no less than three leaves. Springs with many leaves are sometimes used for heavy loads, but they are economical only where use of short springs leads to definite savings in the supporting structure.

Leaf Springs for Vehicle Suspension. Leaf springs are most frequently used in vehicle suspension. The characteristics of a suspension system are affected chiefly by the spring rate and the static deflection.

The rate, or more accurately the load rate, of a spring is the change of load per inch of deflection. This is not the same at all positions of the spring and is different for the spring alone and for the spring as installed. The static deflection of a spring equals the static load divided by the rate at static load; it determines the stiffness of the suspension and the ride frequency of the vehicle. In most cases, the static deflection differs from the actual deflection of the spring between zero load and static load due to influences of spring camber and shackle effect.

A soft ride generally calls for a large static deflection of the suspension. There are, however, other considerations and limits, such as the following:

- A more flexible spring will have a larger total deflection and will be heavier
- In most applications, more flexible spring will cause more severe striking through or will require a larger ride clearance (the spring travel on the vehicle from the design load position to the metal-to-metal contact position), disregarding rubber bumpers
- The change of standing height of the vehicle due to a variation of load is larger with a more flexible spring

The static deflection to be used also depends on the available ride clearance. Further, the permissible static deflection depends on the size of the vehicle because of considerations of stability in braking, accelerating, cornering, and so on.

Table 15 lists typical static deflections and ride clearances for various types of vehicles. These values are approximate and are meant to be used only as a general indication of current practice in suspension system design.

Table 15 Static deflections and ride clearances of various types of vehicles with steel leaf springs

Type of vehicle and load	Static deflection		Ride clearance	
	mm	in.	mm	in.
Passenger automobiles, at design load	100-300	4-12	75-125	3-5
Motor coaches, at maximum load	100-200	4-8	50-125	2-5
Trucks, at rated load				
For highway operation	75-200	3-8	75-125	3-5

The weight of a spring for a given maximum stress is determined by the energy that is to be stored; this energy is represented by the area under a load-deflection diagram. The effects of changes in rate and clearance on the weight of the spring can easily be seen in this type of diagram.

Figure 23 shows theoretical load-deflection diagrams for two springs designed for the same load and ride clearance; the spring represented by the solid line in Fig. 23(a) is stiffer than the optimum spring for these design conditions, while the spring represented by the solid line in Fig. 23(b) is too flexible. Each spring, when fully deflected, stores the same amount of energy (1020 J, or 9000 in. · lbf), and the two springs will weigh almost the same if made of the same kind of material. The optimum spring (minimum energy and weight) for this design load and ride clearance will have stiffness intermediate between those of the two springs represented in Fig. 23. For this optimum spring, static deflection is equal to ride clearance, as indicated by the dashed lines in Fig. 23; the stored energy for this spring is only 900 J (8000 in. · lbf). Figure

23 also indicates that a change in ride clearance will affect the stored energy, and therefore the required weight, of the stiff spring much more than those of the flexible spring.

Fig. 23 Theoretical load-deflection diagrams for two leaf springs. In each diagram, the dashed line represents the minimum-energy spring having the same design load and ride clearance as the spring represented by the solid line.

Steel Grades. The basic requirement of a leaf-spring steel is that it have sufficient hardenability relative to leaf thickness to ensure a fully martensitic structure throughout the entire cross section. Nonmartensitic transformation products detract from the fatigue properties. Automotive chassis leaf springs have been made from various fine-grain alloy steels such as grades 9260, 4068, 4161, 6150, 8660, 5160, and 51B60.

In the United States, almost all leaf springs are currently made of chromium steels such as 5160 or 51B60, or their H equivalents. With 5160, the chemical composition is specified as an independent variable (while the hardenability of the steel is a dependent variable that will vary with the composition); 5160H is essentially the same steel except that the hardenability is specified as an independent variable (while the composition is a dependent variable that can be adjusted to meet the hardenability-band requirement).

In general terms, higher alloy content is necessary to ensure adequate hardenability when thicker leaf sections are used. When considering a grade of steel, it is recommended that hardenability be either calculated from chemical composition or (for the various H steels) determined from the hardenability-band charts in the article "Hardenability Curves" in this Volume. The following rule of thumb may be useful for correlating section size and steel grade:

Maximum section thickness	Steel
---------------------------	-------

mm	in.	
8.2	0.323	5160
15.9	0.625	5160H
36.6	1.440	51B60H

Mechanical Properties. Steels of the same hardness in the tempered martensitic condition have approximately the same yield and tensile strengths. Ductility, as measured by elongation and reduction in area, is inversely proportional to hardness. Based on experience, the optimum mechanical properties for leaf-spring applications are obtained within the hardness range 388 to 461 HB. This range contains the six standard Brinell hardness numbers 388, 401, 415, 429, 444, and 461 (corresponding to the ball-indentation diameters 3.10, 3.05, 3.00, 2.95, 2.90, and 2.85 mm obtained with an applied load of 3000 kgf). A specification for leaf springs usually consists of a range covered by four of these hardness numbers, such as 415 to 461 HB (for thin section sizes). Typical mechanical properties of leaf-spring steel are as follows:

Tensile strength, MPa (ksi)	131-1690 (190-245)
Yield strength (0.2% offset), MPa (ksi)	1170-1550 (170-225)
Elongation, %	7 minimum
Reduction in area, %	25 minimum
Hardness	42-49 HRC, or 338-461 HB for 3000 kg load (3.10-2.85 mm indentation diameter)

Mechanical Prestressing. Presetting, shot peening, and/or stress peening at ambient temperatures produces large increases in fatigue durability without increasing the size of the spring. These prestressing methods are more effective in increasing the fatigue properties of a spring than are changes in material.

When a load is applied to a leaf spring, the surface layers are subjected to the maximum bending stress. One surface of each leaf is in tension, and the other surface is in compression. The surfaces that are concave in the free position are generally tension surfaces under load, while the convex surfaces are generally in compression. Fatigue failures of the leaves start at or near the surface on the tension side. Because residual stresses are algebraically additive to load stresses, the introduction of residual compressive stresses in the tension surface by prestressing reduces operating stress level, thus increasing fatigue life.

Presetting (also known as cold setting, bulldozing, setting-down, scragging) produces residual compressive stresses in the tension surface and residual tensile stresses in the compression surface by forcing the leaves to yield or take a permanent set in the direction of subsequent service loading. Although this operation is beneficial to fatigue life, its primary effect is the reduction of settling (load loss) in service. Presetting is usually done after assembly.

Shot peening introduces compressive residual stresses by subjecting the tension side of each individual leaf to a high-velocity stream of shot. The SAE Manual on Shot Peening, HS-84, deals with the control of process variables, while techniques for control of peening effectiveness and quality are explained in Procedures for Using Standard Shot Peening

Test Strip, SAE J443. Cut wire shot, sizes CW-23 to CW-41, and cast steel shot, sizes S-230 to S-390, are generally used for this purpose. The intensity of shot peening applied to light-weight and medium-weight springs is usually in the range of 0.25 to 0.50 mm (0.010 to 0.020 in.) as measured by Almen "A" strip. For heavy springs, single-leaf springs, and stress-peened springs, the intensity is usually 0.15 to 0.35 mm (0.006 to 0.014 in.), as measured by Almen "C" strip. Coverage in both cases should be at least 90%.

Stress peening (strain peening) is a means of introducing higher residual compressive stresses than are possible with shot peening with the leaf in the free (unloaded) position. Stress peening is done by shot peening the leaf while it is loaded (under stress) in the direction of subsequent service loading.

Curvature of a leaf spring will be changed by mechanical prestressing. The magnitude of the changes due to shot peening and presetting can be calculated using the formulas given in SAE Information Report J788a. The stress patterns induced by these processes are compared schematically in Fig. 24. The effects of presetting and shot peening are cumulative to some extent, but the results may be influenced by the sequence of operations.

Fig. 24 Beneficial stress patterns induced by presetting and peening

Surface Finishes and Protective Coatings. Surface finish is defined as the surface condition of the spring leaves after the steel has been formed and heat treated, and prior to any subsequent coating treatment. Normally, automotive leaves are utilized as heat-treated or in the shot-peened condition. An as-heat-treated finish will be a tight oxide produced by the quenching and tempering operations and will exhibit a blue or blue-black appearance. A shot-peened finish is the result of removing the blue or blue-black color by the peening operation and is characterized by a matte luster appearance.

A protective coating is a material added to the surfaces of individual leaves or to the exposed areas of leaf-spring assemblies. Its primary purpose is to prevent corrosion both in storage and in operational environments. All exposed surfaces to be coated must be free of loose scale and dirt. Peened surfaces should be coated as soon as possible to prevent the formation of corrosion. It is important that an enveloping coat be applied. An unprotected area or a break in the coating may contribute to localized corrosion and a reduction in fatigue life. Before a coating is specified, whether grease,

oil, paint, or plastic, it should be evaluated for effects that its application might have on the fatigue life of the spring steel. The thickness and adhesion characteristics of the coating must be within the tolerances that have been established for the type of material being used in order to provide adequate corrosion protection and to ensure satisfactory performance.

Steel Tubular Products

Revised by Dennis Smyth, The Algoma Steel Corporation Ltd.; R.G. Lessard, Stelpipe, a Unit of Stelco, Inc.; and Frank Minden, Lone Star Steel

Introduction

STEEL TUBULAR PRODUCTS is the term used to cover all hollow steel products. Although these products are usually produced in cylindrical form, they are often subsequently altered by various processing methods to produce square, oval, rectangular, and other symmetrical shapes. Such products have applications that are almost innumerable, but they are most commonly used as conveyors of fluids and as structural members.

The products discussed in this article are those made from wrought carbon or alloy constructional steels and designated by the terms pipe, specialty tubing, and oil country tubular goods. Excluded are stainless steel items in the categories mentioned above and hollow steel products used as containers for storage and shipping.

In discussing the various tubular items in this article, emphasis is given to product classifications, available specifications, chemical compositions, sizes, and other dimensional characteristics. For more information on many of the manufacturing practices used in making steel tubular products, the reader may refer to Ref 1 and 2 and to *Forming and Forging*, Volume 14 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Product Classification

The two simplest and broadest commercial classifications of steel tubular products are tube and pipe. (Although the application of the terms pipe and tube is not always consistent, the term pipe is commonly used to describe cylindrical tubular products made to standard combinations of outside diameter and wall thickness.) These two broad classifications are subdivided into several named use groups. For example, the term tube covers three such groups: pressure tubes, structural tubing, and mechanical tubing.

The term pipe covers five such groups: standard pipe, line pipe, oil country tubular goods, water well pipe, and pressure pipe. There is also pipe for special applications, such as conduit pipe and tubular piling, that do not fit any of these

classifications. Each of these use groups, in turn, has a number of uses or named-use subdivisions. These are shown in Table 1 and described in a subsequent section of this article.

Table 1 Major types and uses of pipe

Type of pipe	Uses
Standard	Industrial or residential water steam, oil, or gas transmission; distribution or service lines; structural uses
Special	Conduit, piling, pipe for nipples, and so on
Line	Oil- or gas-transmission pipe, water-main pipe
Oil country tubular goods	Drill pipe, casing, tubing
Water well	Drive pipe, driven-well pipe, casing, reamed, and drifted pipe
Pressure	Pipe for elevated-temperature or pressure service

The named uses in Table 1 have been developed without regard to method of manufacture, size range, wall thickness, or degree of finish. For example, the names do not distinguish between those products commonly called pipe that have size and wall thicknesses the same as standard pipe, and those having different basic dimensions; all are termed pipe.

On a use basis, pressure pipe is distinguished from pressure tubes in that the latter are suitable for those applications in which heat is applied externally. The principal use groups and types of pressure tubes are shown in Table 2.

Table 2 Principal uses and types of pressure tubes

Use groups	Types
Water tube boilers	Generating tubes, superheater tubes, economizer tubes, circulator tubes, furnace wall tubes
Fire tube boilers	Boiler flues, superheater flues, superheater tubes, arch tubes, stay tubes, safe ends
Others	Feedwater heater tubes, oil still tubes

Structural and mechanical tubing do not follow this system of nomenclature. Instead, their names are derived from the method of fabrication and degree of finish, such as cold formed welded or seamless hot finished.

Steel tubular products can be made by forming a flat skelp, sheet, strip, or plate into a hollow cylinder and welding the resulting longitudinal seam together or by generating an opening in a solid cylinder by piercing and elongating the resultant hollow cylinder. The first group of products is called welded, and the second group, seamless. The processes for producing these products are discussed in the following sections.

Welding Processes

In producing welded steel tubular products, flat-rolled skelp, strip, sheet, or plate is formed into cylinders that are then joined at the longitudinal or spiral seam by one of the processes described below.

Electric resistance welding employs a series of operations, in the first of which the flat-rolled steel is cold shaped into tubular form. Welding is effected by the application of pressure and heat generated by induction or by an electric current through the seam. The welding pressure is generated by constricting rolls and the electromagnetic effects of the high welding current. Electric resistance welded tubular products having longitudinal seams are usually made in sizes ranging from 3.2 mm ($\frac{1}{8}$ in.) nominal to 0.6 m (24 in.) actual outside diameter, but larger sizes are also available. Electric resistance methods are also sometimes used for making tubular products by spiral welding. This method is frequently used for large-diameter products.

Continuous Welding. In continuous (or furnace butt) welding, skelp with square or slightly beveled edges is furnace heated to the welding temperature. The heated stock is roll formed into cylindrical shape as it emerges from the furnace; additional heat is usually provided by an oxygen or air jet impinging on the seam edges, and the tube passes through constricting rolls where the seam edges are welded by the pressure of the rolls. Continuous welded products are available in nominal diameters from 3.2 to 100 mm ($\frac{1}{8}$ to 4 in.).

Fusion Welding. In fusion welding, the flat-rolled steel, with edges suitably prepared, is formed into tubular shape by either hot or cold shaping. The flat-rolled steel may be shaped longitudinally (straight seam) or bent into helical form (spiral welded). The edges are welded with or without simultaneously depositing filler metal in a molten or molten-and-vapor state. Mechanical pressure is not required to effect welding. Fusion may be accomplished by either electric arc or gas heating, or a combination of both. The upper limit of outside diameter is determined mainly by the forming method and the fusion welding process used.

Double submerged arc welding is a special method of shielded-arc welding in which the seam is submerged under a solid flux while being welded. The weld is made in two passes, one from inside the pipe and the other from outside the pipe, with approximately half the wall thickness being welded in each pass. The maximum diameter is limited only by the capability of the forming equipment, and double submerged-arc welded pipe is currently available in outside diameters of up to 3 m (120 in.).

Seamless Processes

Steel tubular products produced by the seamless processes are made in diameters up to $\frac{2}{3}$ m (26 in.) by the rotary piercing method and up to 1.2 m (48 in.) by hot extrusion.

Rotary Piercing. In rotary piercing, rounds of the necessary diameter and length are first heated to rolling temperature. Each hot round is fed into a set of rolls having crossed axes and surface contours that pull it through the rolls, thus rupturing it longitudinally. The force of the rolls then causes the metal to flow around a piercing point, enlarging the axial hole, smoothing the inside surface, and forming a tube. After being pierced, the rough tube is usually hot rolled to final dimensions by means of plug mills or mandrel mills, which may be followed by stretch reducing mills.

Hot extrusion is a hot working process for making hollows, suitable for processing into finished tubing of regular and irregular form, by forcing hot, prepierced billets through a suitably shaped orifice formed by an external die and internal mandrel. The outside of the hollow acquires the size and contour imposed by the die; the inside conforms to the size and contour of the mandrel. Extruded hollows may be further worked into tubular products by cold-finishing methods.

Cupping and Drawing. In the cupping and drawing method of making seamless tubing, a circular sheet or plate is hot cupped in a press through several pairs of conical dies, each successive pair being deeper and more nearly cylindrical than the previous set. The rough tube then is drawn to finished size.

Cold Finishing

Pipe in suitable sizes and most products classified as tubing, both seamless and welded, may be cold finished. The process may be used to increase or decrease the diameter, to produce shapes other than round, to produce a smoother surface or

closer dimensional tolerances, or to modify mechanical properties. The process most commonly used is cold drawing, in which the descaled hot-worked tube is plastically deformed by drawing it through a die and over a mandrel (mandrel drawing) to work both exterior and interior surfaces. Cold drawing through the die only (without a mandrel) is called sink drawing or sinking.

Tube Reducing and Swaging. In tube reducing by rotorolling or pilgering and in swaging, a reducing die works the tube hollow over a mandrel; swaging may, however, be done without a mandrel. The commercial importance of tube reducing is, first, that very heavy reductions (up to 85%) can be applied to mill length tubes, and second, that the process can be applied to the refractory alloys that are difficult to cold draw because of high power requirements.

Cold Finishing. Tubular products of circular cross section may be cold finished on the outside by turning, grinding, or polishing, or by any combination of these processes. They may be bored, skived, or honed on the inside diameter. Because these operations involve stock removal only, with negligible plastic deformation, there is no enhancement of mechanical properties.

Many of the standard specifications involving strength are based on the properties of hot-rolled or cold-worked material. Some high-strength oil country goods are heat treated to achieve the combination of high strength, ductility, and sulfide stress corrosion cracking resistance required by the intended application.

Cold drawing may be employed to improve surface finish and dimensional accuracy and to increase the strength of tubular products. Some customer specifications prescribe strength levels that can best be attained by cold working.

Pipe Sizes and Specifications

Pipe is distinguished from tubing by the fact that it is produced in relatively few sizes and, therefore, in comparatively large quantities of each size. Size of pipe is designed according to one of two methods.

It is now recommended that pipe less than 50 mm (2 in.) in diameter have a nominal or named size roughly equal to the inside diameter of standard-weight pipe. The outside diameter of each size is standard, regardless of weight, in order to allow the use of standard thread sizes. Therefore, the increase in wall thickness necessary to produce extra strong and double extra strong weights results in a decrease in inside diameter. The size designation, however, remains the same as for standard-weight pipe of the same outside diameter.

It is further recommended that for diameters of 50 mm (2 in.) and larger the pipe size be designated by outside diameter, wall thickness, and weight per unit length. In previous practice, the lower limits for designation by outside diameter were 90 mm ($3\frac{1}{2}$ in.) for line pipe with plain ends and 355 mm (14 in.) for all threaded pipe. The size of oil country goods is always designated by outside diameter.

For a reasonably complete list of the standardized sizes and weights of pipe for the major named uses, the AISI Steel Products Manual should be consulted. For oil country tubular goods, the specifications of the American Petroleum Institute (API) govern. Table 3 lists the current ASTM, API, and Canadian Standards Association (CSA) specifications covering pipe. Some of these involve several grades. The specifications listed cover carbon and alloy steels other than stainless, all methods of manufacture, and a wide range of service temperature.

Table 3 ASTM, API, and CSA specifications for carbon and alloy steel pipe

Specification	Product
ASTM specifications	
A 53 ^(a)	Welded and seamless steel pipe, black and hot dipped, zinc coated
A 106 ^(a)	Seamless carbon steel pipe for high-temperature service

A 134 ^(a)	Arc-welded steel-plate pipe (sizes 400 mm, or 16 in., and over)
A 135 ^(a)	Resistance-welded steel pipe
A 139	Arc-welded steel pipe (sizes 100 mm, or 4 in., and over)
A 211	Spiral-welded steel or iron pipe
A 252	Welded and seamless steel pipe piles
A 333 ^(a)	Welded and seamless steel pipe for low-temperature service
A 335 ^(a)	Seamless ferritic alloy steel pipe for high-temperature service
A 381	Double submerged-arc welded steel pipe for high-pressure transmission systems
A 405	Seamless ferritic alloy steel pipe, specially heat treated for high-temperature service
A 523	Resistance-welded or seamless steel pipe (plain end) for high-pressure electric cable conduit
A 524 ^(a)	Seamless carbon steel pipe for atmospheric service and lower temperatures
A 587 ^(a)	Resistance-welded low-carbon steel pipe for the chemical industry
A 589	Welded and seamless carbon steel water well pipe
A 671 ^(a)	Arc-welded steel pipe for atmospheric service and lower temperatures
A 672 ^(a)	Arc-welded steel pipe for high-pressure service at moderate temperatures
A 691	Arc-welded carbon or alloy steel pipe for high-pressure service at high temperatures
A 714	Welded and seamless HSLA steel pipe
A 795	Black and hot-dipped zinc-coated (galvanized) welded and seamless steel pipe for fire protection use
API specifications	
2B	Specification for fabricated structural steel and pipe
5CT	Specification for casing and tubing

5D	Specification for drill pipe
5L	Specification for line pipe
CSA standard	
CAN3-Z245.1-M86	Steel line pipe

(a) This ASTM specification is also published by ASME, which adds an "S" in front of the "A" (for example, SA 53).

The situation with respect to the composition and strength required for the various end-uses may be summarized as follows: The simplest specification for pipe is ASTM A 53, which covers material that is produced for all ordinary purposes such as conveying fluids under low pressure that may be bent, coiled, or flanged. Chemical composition is specified, and strength requirements consist of a tension test in addition to the hydrostatic test or optional nondestructive test for seamless pipe.

The chemical composition limits for ASTM, API, and CSA carbon and alloy steel pipe are shown in Table 4 (carbon steel) and Table 5 (alloy steel). The composition limits for the alloy steel pressure pipe covered in several ASTM specifications are shown in Table 6. It should be noted that all of the specifications in Table 3 involve carbon (Table 4) or alloy (Table 5) steels with no more than a medium carbon content (0.50% max). The strength requirements (Table 7) are based on as-rolled material in the common qualities, with the classes being graded upward to annealed, normalized, normalized and tempered, or quenched and tempered properties for the higher qualities. Because ductility is considered desirable at higher strength levels, carbon content is restricted. To achieve such strength levels, alloying elements may be added or heat treatment may be employed. When welding is to be used as a method of joining, there is additional reason for carbon restriction.

- (a) Except for copper, where a single value is shown, it is a maximum limit.
- (b) Open hearth, electric furnace, or basic oxygen.
- (c) Alloy steel grade(s) only.
- (d) Furnace butt or electrical resistance.
- (e) 0.005 min Nb, 0.02 min V, or a combination thereof shall be used at the discretion of the manufacturer.
- (f) Electric resistance or electric flash.
- (g) Nickel, chromium, and copper combined shall not exceed 0.5%.
- (h) Alloys are typically added in various amounts, even though it is not specified in API Specification 5CT.
- (i) Carbon content may be increased to 0.55% max if the product is oil quenched.
- (j) No limits, but must be reported in analysis.
- (k) Cold expanded or nonexpanded.
- (l) Submerged arc, electric resistance, gas metal arc, spiral weld submerged-arc, and double seam.
- (m) Butt weld, electric weld, and submerged-arc weld.
- (n) Pipe meeting the mechanical property requirements but deviating from the above limits may be supplied subject to agreement of purchaser and manufacturer.

(o) Maximum content may be subject to agreement by purchaser and manufacturer.

(p) Maximums are 0.11% Nb, 0.11% V, 0.06% Ti, 0.001% B, and 0.020% (product analysis only) Ce.

(e) Furnace butt, electric resistance, electric flash, or electric induction.

(f) Submerged arc, electric resistance, electric flash, electric induction, or gas metal arc.

(g) Furnace butt, electrical resistance, or submerged-arc weld

Common Types of Pipe

The following brief descriptions concern the end-uses of some of the more common types of pipe.

Standard pipe is standard weight, extra strong, and double extra strong welded or seamless pipe of ordinary finish and dimensional tolerances, produced in sizes up to 660 mm (26 in.) in nominal diameter, inclusive. This pipe is used for fluid conveyance and some structural purposes.

Conduit pipe is welded or seamless pipe intended especially for fabrication into rigid conduit, a product used for the protection of electrical wiring systems. Conduit pipe is not subjected to hydrostatic testing unless so specified. It may be galvanized or bare, as specified. It is furnished in standard weight pipe sizes from 6 to 150 mm ($\frac{1}{4}$ to 6 in.) in lengths of approximately 3 to 6 m (10 or 20 ft), with plain ends or threaded ends, as specified. Conduit pipe comes under the scope of Underwriters Laboratories Inc. Specification UL6 or ANSI standards.

Piling pipe is welded or seamless pipe for use as piles, with the cylinder section acting as a permanent load-carrying member or as a shell to form cast-in-place concrete piles. ASTM A 252 includes three grades, which have different minimum tensile strengths, a variety of diameters, ranging from 150 to 610 mm (6 to 24 in.), and a variety of wall thicknesses. Ends may be plain or beveled for welding.

Pipe for nipples is standard weight, extra strong, or double extra strong welded or seamless pipe, produced for the manufacture of pipe nipples. Pipe for nipples is commonly produced in random lengths with plain ends, in nominal sizes from 3 to 300 mm ($\frac{1}{8}$ to 12 in.). Close outside-diameter tolerances, sound welds, good threading properties, and surface cleanliness are essential in this product. Pipe for oil country tubular good couplings must be manufactured from seamless pipe. It is commonly coated with oil or zinc and is well protected in shipment.

Transmission or line pipe is welded or seamless pipe currently produced in sizes ranging from 3 mm ($\frac{1}{8}$ in.) nominal to 1.2 m (48 in.) actual outside diameter and is used principally for conveying gas or oil. Transmission pipe is produced with ends plain, threaded, beveled, grooved, flanged, or expanded, as required for various types of mechanical couplers or for welded joints. When threaded ends and couplings are required, recessed couplings are supplied. Transmission pipe is covered by API specification 5L and CSA specification Z245.1.

Water main pipe is welded or seamless steel pipe used for conveying water for municipal and industrial purposes. Pipe lines for such purposes are commonly designated as flow mains, transmission mains, force mains, water mains, or distribution mains. The mains are generally laid underground. Sizes range from 40 to 2450 mm ($1\frac{1}{2}$ to 96 in.) in nominal diameter in a variety of wall thicknesses. Pipe is produced with ends suitably prepared for mechanical couplers, with plain ends beveled for welding, or with bell and spigot joints for field connection. Pipe is produced in double random lengths of about 12 m (40 ft), single random lengths of about 6 m (20 ft), or in specified lengths. When required, it is produced with

a specified coating or lining, or both. Steel water main pipe 150 mm (6 in.) in nominal diameter and larger is covered by Standard C200 of the American Water Works Association.

Oil country tubular goods is a collective term applied in the oil and gas industries to three kinds of pipe used in oil wells: drill pipe, casing, and tubing. These products conform to API specifications 5CT (casing and tubing) and 5D (drill pipe). The chemical composition requirements are contained in Tables 4 and 5, and the strength requirements are found in Table 7.

Drill pipe is used to transmit power by rotary motion from ground level to a rotary drilling tool below the surface and to convey flushing media to the cutting face of the tool. Drill pipe is produced in sizes ranging from 60 to 170 mm ($2\frac{3}{8}$ to $6\frac{5}{8}$ in.) in outside diameter. Size designations refer to actual outside diameter and weight per foot. Drill pipe is usually upset, either internally or externally, or both, and is prepared to accommodate welded-on types of joints.

Casing is used as a structural retainer for the walls of oil or gas wells, to exclude undesirable fluids and to confine and conduct oil or gas from productive subsurface strata to ground level. Casing is produced in sizes from 115 to 500 mm ($4\frac{1}{2}$ to 20 in.) in outside diameter. Size designations refer to actual outside diameter and weight per foot. Ends are commonly threaded and furnished with couplings, but may be prepared to accommodate other types of joints.

Tubing is used within the casing of oil wells to conduct oil and gas to ground level. It is produced in sizes from 26 to 114 mm (1.05 to 4.50 in.) in outside diameter, in several weights per foot. Ends are threaded for special integral-type joints or fitted with couplings and may or may not be upset externally.

Water well pipe is a collective term applied to four types of pipe that are used in water wells and that conform to ASTM A 589: type I, drive pipe; type II, reamed and drifted pipe; type III, driven well pipe; and type IV, casing pipe. The chemical composition and strength requirements are given in Tables 4 and 7, respectively.

Drive pipe is used to transmit power from ground level to a rotary drill tool below the surface and to convey flushing media to the cutting face of the tool. The lengths of pipe have specially threaded ends that permit the lengths to butt inside the coupling. Drive pipe is produced in nominal sizes of 150, 200, 300, 350, and 400 mm (6, 8, 12, 14, and 16 in.) in outside diameter.

Driven well pipe is threaded pipe in short lengths used for the manual driving of a drill tool or for use with short rigs. It may be furnished in random lengths ranging from 0.9 to 1.8 m (3 to 6 ft) or in random lengths ranging from 1.8 to 3.0 m (6 to 10 ft).

Casing is used both to confine and conduct water to ground level and as a structural retainer for the walls of water wells. It is produced as threaded pipe in random lengths from 4.9 to 6.7 m (16 to 22 ft) and in sizes from 90 to 220 mm ($3\frac{1}{2}$ to $8\frac{5}{8}$ in.) in outside diameter. In western water well practice, welded strings are sometimes used.

Reamed and drifted pipe is similar to casing, but is manufactured and inspected in a manner that assures the well driller that the pipe string will have a predetermined minimum diameter sufficient to permit unrestricted passage of pumps or other equipment through the string. The pipe is threaded and is produced in a wider range of sizes--25 to 300 mm (1 to 12 in.) in outside diameter--than standard water well casing.

Pressure pipe, as distinguished from pressure tubes, is a commercial term for pipe that is used to convey fluids at elevated temperature or pressure, or both, but that is not subjected to the external application of heat. This commodity is not differentiated from other types of pipe by ASTM, and the applicable specifications are listed with the other types in Table 3. Pressure pipe ranges in size from 3 mm ($\frac{1}{8}$ in.) nominal to 660 mm (26 in.) actual outside diameter in various wall thicknesses. Pressure pipe is furnished in random lengths, with threaded or plain ends, as required.

Pressure Tubes

Pressure tubes are given a separate classification by both ASTM (Table 8) and the producers. The chemical composition limits are shown in Table 9 for carbon steel and in Tables 6 and 10 for alloy steel; the strength requirements are shown in Tables 11 and 12. Pressure tubes are distinguished from pressure pipe in that they are suitable for the application of external heat while conveying pressurized fluids.

Table 8 Specifications for carbon and alloy steel pressure tubes (ASTM)

Specification	Product
A 161	Seamless low-carbon or carbon-molybdenum steel still tubes for refinery service
A 178 ^(a)	Resistance-welded carbon and carbon-manganese steel boiler tubes
A 179 ^(a)	Seamless cold-drawn low carbon steel heat-exchanger or condenser tubes
A 192 ^(a)	Seamless carbon steel boiler tubes for high-pressure service
A 199 ^(a)	Seamless cold-drawn intermediate alloy steel heat-exchanger or condenser tubes
A 200	Seamless intermediate alloy steel still tubes for refinery service
A 209 ^(a)	Seamless carbon-molybdenum alloy steel boiler and superheater tubes
A 210 ^(a)	Seamless medium-carbon steel boiler and superheater tubes
A 213 ^(a)	Seamless ferritic and austenitic alloy steel boiler, superheater, and heat-exchanger tubes
A 214 ^(a)	Resistance-welded carbon steel heat-exchanger and condenser tubes
A 226 ^(a)	Resistance-welded carbon steel boiler and superheater tubes for high-pressure service
A 250 ^(a)	Resistance-welded ferritic alloy steel boiler or superheater tubes
A 254	Copper-brazed steel tubes for general engineering use as fluid lines
A 334 ^(a)	Welded and seamless carbon and alloy steel tubes for low-temperature service
A 423 ^(a)	Resistance-welded or seamless low-alloy steel tubes for applications where corrosion resistance is important
A 539	Resistance-welded coiled steel tubes for gas or fuel oil lines
A 556 ^(a)	Seamless cold-drawn carbon steel feed water heater tubes

A 557 ^(a)	Resistance-welded carbon steel feed water heater tubes
A 692	Seamless medium-strength carbon-molybdenum alloy steel boilers and superheater tubes

(a) This specification is also published by ASME, which adds an "S" in front of the "A" (for example, SA 178)

(d) Heat treated

The principal named uses of pressure tubing are given in Table 2. These tubings are produced to actual outside diameter and minimum or average wall thickness (as specified by the purchaser) and may be hot finished or cold finished, as specified.

Double-wall brazed tubing is a specialty tubing confined to small sizes (see ASTM A 254). It is used in large quantities by the automotive industry for brake lines and fuel lines, and by the refrigeration industry for refrigerant lines. It is made by forming copper-coated strip into a tubular section with double walls, using either single-strip or double-strip construction. The tubing is then heated in a reducing atmosphere to join all mating surfaces completely. The resulting product is thus copper coated both inside and outside. When required by the intended service, a tin coating may be supplied. Available sizes range from 3 to 15 mm ($\frac{1}{8}$ to $\frac{5}{8}$ in.) in outside diameter (OD) with wall thickness from 0.64 mm

(0.025 in.) for 3 mm ($\frac{1}{8}$ in.) OD to 0.9 mm (0.035 in.) for 15 mm ($\frac{5}{8}$ in.) OD (SAE Handbook). The product is generally made to fractional-inch sizes for use with standard compression fittings. It may be sink drawn for the improvement of surface finish and tolerances.

Structural Tubing

Structural tubing is used for the welded, riveted, or bolted construction of bridges and buildings and for general structural purposes. It is available as round, square, rectangular, or special-shape tubing, as well as tapered tubing. These products are covered by ASTM specifications (see Table 13). Structural tubing is produced with a maximum wall thickness of 13 mm (0.500 in.) and with maximum circumferences of 810 mm (32 in.) for seamless tubes and 1220 mm (48 in.) for welded tubes. The chemical composition limits and strength requirements are given in Tables 14 and 15, respectively.

(b) Tube shapes other than round

Mechanical Tubing

Mechanical tubing includes welded and seamless tubing used for a wide variety of mechanical purposes. It is usually produced to meet specific end-use requirements and therefore is produced in many shapes, to a variety of chemical compositions and mechanical properties, and with hot-rolled or cold-finished surfaces. Most mechanical tubing is ordered to ASTM specifications (see Table 13). Even when customer specifications are used, they usually reference portions of the ASTM Standard.

Mechanical tubing is not produced to specified standard sizes; instead, it is produced to specified dimensions, which may be anything the customer requires within the limits of production equipment or processes. Controlling tolerances are placed on outside diameter and wall thickness for hot-finished tubing and on outside diameter, inside diameter, and wall thickness for cold-finished tubing. Size is usually expressed in inches and decimals, but metric dimensions can be specified. Specifications for size may include any two of the controlling dimensions--outside diameter, inside diameter, and wall thickness--but never all three.

The chemical compositions commonly available in steel mechanical tubing cover a wide variety of standard AISI/SAE grades. In addition to the standard grades, numerous high-strength low-alloy grades and unique chemistries are produced to customer specifications. When the steel used, either carbon or alloy steel, requires normalizing or annealing after welding, such operations become a part of the specification. For example, a type of welded structural tubing made from carbon steel with nominal carbon content of 0.50% is usually furnished normalized.

Welded mechanical tubing is usually made by electric resistance welding, but some is made by the various fusion welding processes. In all instances, the exterior welding flash may be removed (if necessary) by cutting, grinding, or hammering.

Electric resistance welded (ERW) mechanical tubing is made from hot-rolled or cold-rolled carbon steel or from alloy steel strip. The welded tubing can be supplied as-welded, hot finished, or cold finished. Hot-finishing operations usually consist of either a stretch reducing mill or a hot reducing mill (hot sinking). Microstructural and hardness variations associated with the welding are modified by either seam annealing the weld zone or full body normalizing the entire tube.

Sizes produced by electric resistance welding range in outside diameter from 6.4 to 400 mm ($\frac{1}{4}$ to 16 in.) and in wall thickness from 1.65 to 17 mm (0.065 to 0.680 in.) for hot-rolled steel and 0.65 to 4.2 mm (0.025 to 0.165 in.) for cold-rolled steel. Hydraulically or electrically driven stretch reducing mills accomplish tube elongation, reduction in diameter, and control of wall thickness on very long mill lengths in essentially a continuous process. Walls as thick as 18 mm (0.72 in.) are commercially available within limited outside diameter ranges.

Continuous-welded cold-finished mechanical tubing, as its name implies, is tubing that has been hot formed by furnace butt welding and cold finished. It is furnished sink drawn or mandrel drawn and is available in outside diameters up to 90 mm ($3\frac{1}{2}$ in.) and wall thicknesses from 0.9 to 13 mm (0.035 to 0.500 in.). The material is low-carbon steel, and the product is, in effect, a form of cold-drawn pipe. Although furnished in a narrower size range than electric resistance welded tubing, it has two advantages: within the available size range, heavier walls are available, and there is no problem with flash.

Seamless mechanical tubing, both hot and cold finished, is available in a wide variety of finishes and mechanical properties. It is made from carbon and alloy steels in sizes up to and including 325 mm ($12\frac{3}{4}$ in.) in outside diameter.

Hot-finished seamless tubing is produced by rotary piercing or extrusion processes. Therefore, it has surfaces similar to the surface regularly produced on hot-rolled steel and, in general, cannot be held to dimensional tolerances as close as those of tubing produced by cold finishing. It is produced in sizes as small as 38 mm ($1\frac{1}{2}$ in.) in outside diameter.

Cold-finished mechanical tubing can be produced by means of surface removal or by cold working. Surface removal includes turning, polishing, grinding, or machining. Cold working involves cold reducing to effect changes in cross-sectional dimensions. Drawing over a mandrel (DOM) is the most common method of cold working mechanical tubing. Tubing is prepared for drawing by first pointing it. The end of the tube is mechanically reduced in outside diameter to allow the end to pass through the die for gripping. Tubing must be pickled and lubricated before drawing. Pickling is typically accomplished by hydrochloric or sulfuric acid immersion. A subsequent phosphate immersion coating on the steel surface acts as a binder for the soaplike lubricant. Complete coverage of both the inside and outside diameter is required to prevent galling and chatter during drawing. Several draw benches with 4×10^6 N (1×10^6 lbf) pulling force exist in the industry. Reductions in cross-sectional area of 10 to 30% are common. Drawing is usually followed by a thermal treatment, straightening, and nondestructive inspection.

Cold working and surface removal are used primarily for the purpose of obtaining smaller outside diameters (down to 3.2 mm, or $\frac{1}{8}$ in.), better finishes, thinner walls, and closer dimensional accuracy than is possible in hot-finished tubing. In addition, cold-worked tubing offers improved mechanical properties and machinability. Cold working can also be used to produce tubes having cross-sectional shapes other than round. Cold-drawn tubing can be provided in the as-drawn, cold-worked condition, or thermally treated to the desired combination of mechanical properties or microstructure. Typical thermal treatments available are stress relief annealed, normalized, soft annealed, or quenched and tempered.

Square, rectangular, and special-shape sections are produced in welded or seamless tubing, starting with either round tubing of the required diameter and wall thickness or square, unwelded tubing.

Squaring is done in a Turk's head or by other cold-working methods. A Turk's head consists of a frame in which are mounted four rolls with their axes at 90° and adjusted so that the roll surfaces form an opening of the same shape as the section to be formed. The Turk's head is mounted on a draw bench, and the round tubes are passed through the rolls in the same manner as they are passed through dies.

When Turk's head shaping will not provide close enough tolerances on either the outside or inside of uniformly rounded corners, or close enough diagonal dimensions, the forming is customarily accomplished by means of die-and-mandrel shaping. The corners of sections processed by this means are approximately 90° arcs and have greater uniformity throughout than is provided by Turk's head shaping. Sections that can be processed in this manner are somewhat limited with respect to diameter, wall thickness, and outside and inside corner radii.

In addition to providing square and rectangular tubing, many producers of welded or seamless tubing supply a variety of special sections, such as oval, streamline, hexagonal, octagonal, round inside and hexagonal or octagonal outside, ribbed inside or out, triangular, round-ended rectangular, and D-shape. Available manufacturing equipment limits the size range and sections available from the various producers. These special sections may be made by passing round tube through Turk's head rolls or through a die with or without the use of a mandrel. Because the sections are special, dies and other tools are not kept available. Therefore, when inquiring about shapes other than square or rectangular, it is essential to give full details regarding dimensions and finish.

Closed-Die Forgings

Revised by James A. Rossow, Wyman-Gordon Company

Introduction

FORGING is the process of working hot metal between dies, usually under successive blows and sometimes by continuous squeezing. Closed-die forgings, hot upset parts, and extrusions are shaped within a cavity formed by the closed dies.

Justification for selecting forging in preference to other, sometimes more economical, methods of producing useful shapes is based on several considerations. Mechanical properties in wrought materials are maximized in the direction of major metal flow during working. For complex shapes, only forging affords the opportunity to direct metal flow parallel to major applied service loads and to control, within limits, the refinement of the original ingot structures. Refinement of microstructure is a function of the temperature, the direction, and the magnitude of reduction from the cast ingot to the forged shape. Maximizing the structural integrity of the material permits refinement of design configuration, which in turn permits reduction of weight.

Adequate control of metal flow to optimize properties in complex forging configurations generally requires one or more upsetting operations prior to die forging and may require hollow forging or back extrusion to avoid flash formation at die parting lines. The additional operations and equipment required for hollow forging involve significant cost considerations, which must be justified by improved load capability of the forged part.

Types of Forgings

Forgings are classified in several ways, beginning with the general classifications open die and closed die. They are also classified in terms of the close-to-finish factor, or the amount of stock (cover) that must be removed from the forging by machining to satisfy the dimensional and detail requirements of the finished part (Fig. 1). Finally, forgings are further classified in terms of the forging equipment required for their manufacture, such as, for example, hammer upset forgings, ring-rolled forgings, and multiple-ram press forgings.

Fig. 1 Schematic composite of cross sections of blocker-type, conventional, and precision forgings

Of the various classifications, those based on the close-to-finish factor are most closely related to the inherent properties of the forging, such as strength and resistance to stress corrosion. In general, the type of forging that requires the least machining to satisfy finished-part requirements has the best properties. Thus, a finished part machined from a blocker-type forging usually exhibits mechanical properties and corrosion characteristics inferior to those of a part made from a close-tolerance, no-draft forging.

It should be anticipated that decreasing the amount of stock that must be removed from the forging by machining will almost invariably result in increased die costs. Also, equipment capacity requirements can be increased to produce a forging that is essentially net forged, or closer to finished dimensions. For example, when a window-frame forging was made as a conventional forging, requiring extensive subsequent machining, the frame could be readily produced by blocking and finishing in a 45 MN (5000 tonf) press. However, when the window-frame forging was produced as a close-tolerance, no-draft forging requiring no subsequent machining other than the drilling and re-arming of fastener holes, a 73 MN (8000 tonf) press was required.

Selection of Steel

Selection of a steel for a forged component is an integral part of the design process, and acceptable performance is dependent on this choice. A thorough understanding of the end use of the finished part will serve to define the required mechanical properties, surface finish requirements, tolerance to nonmetallic inclusions, and the attendant inspection methods and criteria.

Steels of forging quality are produced to a wide range of chemical compositions by electric furnace, open hearth, or pneumatic steelmaking processes. With each of the melting and rolling practices, a level of testing and evaluation of quality is exercised. The details of testing and quality evaluation may vary from producer to producer and should be a point of inquiry when forging stock is ordered. Should the designer require it, one or more special quality restrictions can be specified. These will bring into effect additional qualification testing by the producing mill.

Although electric furnaces have the ability to produce forging-quality material by a single slag melting practice, they are generally associated with the production of aircraft-quality alloy steels. High-strength alloy steels, because of their intolerance to inclusions, require this level of refinement to reduce the occurrence of nonmetallics (see the article "High-Strength Low-Alloy Steel Forgings" in this Volume). Occasionally, for higher-reliability applications, it is necessary to specify vacuum arc remelt or electroslag remelt steel. Steels produced to these quality levels are subject to highly restrictive evaluation procedures.

Microalloyed High-Strength Low-Alloy (HSLA) Steels. The use of microalloyed steels has evolved in recent years as an alternative to iron castings for applications such as automotive crankshafts. These steels typically have small additions of vanadium or niobium (0.05 to 0.10%) and can achieve acceptable properties in the non-heat-treated (as-forged) condition. Consequently, these alloys retain the advantages of the forging process while being economically competitive with castings because of the elimination of the heat-treat cycle.

Precipitation-Hardenable Stainless Steels. At the more demanding end of the spectrum for steel forgings is the series of precipitation-hardenable stainless steels such as 15-5PH and PH 13-8Mo. These materials provide an excellent combination of high strength, toughness, and corrosion resistance. These alloys are generally produced as vacuum induction melted plus consumable electrode remelted products. The hardening mechanism includes solution heat treating and cooling at a rate sufficient to retain solute atoms or compounds in the supersaturated state. The forgings are usually supplied in this condition to facilitate subsequent machining operations. At the final stages of fabrication and assembly, the material is then aged or precipitation hardened to develop its desired strength, toughness, and corrosion resistance. Forgings produced from this family of alloys are typically utilized in the most demanding applications, such as aerospace and marine environments.

Forgeability is the relative ability of a steel to flow under compressive loading without fracturing. Except for resulfurized and rephosphorized grades, most carbon and low-alloy steels are usually considered to have good forgeability. Differences in forging behavior among the various grades of steel are small enough that selection of the steel is seldom affected by forging behavior. However, the choice of a resulfurized or rephosphorized steel for a forging is usually justified only if the forging must be extensively machined; because one of the principal reasons for considering manufacture by forging is the avoidance of subsequent machining operations, this situation is uncommon.

Design Requirements. The selection of a steel for a forged part usually requires some compromise between opposing factors--for example, strength versus toughness, stress-corrosion resistance versus weight, manufacturing cost versus useful load-carrying ability, production cost versus maintenance cost, and the cost of the steel raw material versus the total manufacturing cost of the forging. Material selection also involves consideration of melting practices, forming methods, machining operations, heat treating procedures, and deterioration of properties with time in service, as well as the conventional mechanical and chemical properties of the steel to be forged.

An efficient forging design obtains maximum performance from the minimum amount of material consistent with the loads to be applied, producibility, and desired life expectancy. To match a steel to its design component, the steel is first appraised for strength and toughness and then qualified for stability to temperature and environment. Optimum steels are then analyzed for producibility and finally for economy. Table 1 lists typical requirements needed to produce a cost-effective forging that meets customer specifications. Property requirements can be matched to candidate steels by consulting references on material properties available for standard steels.

Table 1 Factors to be considered in the design of efficient forgings

Pattern of applied loads
Uniaxial loads. Tensile or compressive, or reversible with changes in operating conditions
Multiaxial or combined loads. Tensile, compressive, shear, bending, torsion, and bearing. These can be either parallel to a central axis or at an angle. Stress concentration should be minimized in design by specifying smooth, contoured fillets at changes of configuration. Where stress concentration cannot be avoided, notch toughness is usually important in material selection.
Cyclic loads. These can be either high- or low-cycle loads.
Sustained loads. If these loads are tensile, they may accelerate stress corrosion. Interference fits and residual stresses may give rise to sustained loading.
Thermal loads. These are caused by changes in temperature.
Load magnitudes and conditions of loading
Magnitudes
Rate of load application. Gradual or impact
Temperature. The major time accumulations should be estimated for minimum, normal, and maximum temperatures.
Environment. Cyclic periods of atmospheric condensation, chemical composition of environment, circumstances of corrosion, abrasion, erosion, or other wear
Life expectancy or reliability
Service life, including downtime, should be estimated. Repairability should be considered.
Special mechanical, physical, or chemical requirements, if any

Failure analyses are a useful data source for matching the properties of steels to requirements. Failure of a component can occur during operation within the design stress range. One cause of premature failure is lack of proper orientation of a critical design stress with the preferred grain flow of a forging (see the section "Mechanical Properties" in this article).

Unpredicted failure may also occur because of the deterioration of properties with time and service. For example, stress-corrosion cracking, which results from sustained tensile stress, may occur even in a typical ambient atmosphere. Under these conditions, failure is most likely to occur at locations in the forging that coincide with exposed end grain. Failure analyses may uncover other causes of premature failure, such as excessive grain growth, inclusions of nonmetallic impurities, grain flow folding from improper forging practice, lack of a wrought metallurgical structure, and the inadvertent production of stress raisers by machining to an overly sharp fillet or by poor fit in assembly.

The cost of steel as a percentage of the total manufacturing cost of forgings is shown in Fig. 2. These curves are based on an average of many actual forgings that are different in number of forging and heat-treating operations required, cost

of steel, quantity, and setup cost. It should not be inferred from these data that an average 14 kg (30 lb) stainless steel forging will cost 34% more than an average carbon steel forging of the same weight.

Fig. 2 Cost of steel as a percentage of total cost of forgings

controls all processes employed in the production of a forging, from the selection of raw material to final heat treatment and finish machining. It also establishes manufacturing standards to ensure reproducibility in processing and product uniformity. Material control depends on the proper application of drawings, specifications, manufacturing process controls, and quality assurance programs to satisfy all requirements for metallurgical integrity, mechanical properties, and dimensional accuracy. It can also provide for identification and certification of the forging so that it can be traced throughout processing and in service.

Responsibility for material control is subject to agreement between the purchaser and forging supplier. In many such agreements, the purchaser is responsible for design, material selection, and controls during manufacture; the forging supplier is responsible for maintaining adequate process control and inspection. The liability of the forging supplier is often limited to the replacement of forgings that have failed or have not met specifications.

Material Specification. As part of his responsibility for material selection, the purchaser (or designer) frequently prepares specifications or drawings that indicate the specific locations at which test specimens shall be removed from the forging and that will prescribe the nature and frequency of tests. Standard specifications are used for established materials with well-known mechanical properties. When advanced materials or processes, for which standard specifications are unavailable, are selected, it is the designer's responsibility to ensure that appropriate quality assurance procedures are established and incorporated into the purchase agreement.

Quality Assurance and Quality Control. For the forging supplier, material control encompasses quality assurance and quality control. Quality assurance consists of the tests and surveillance required to assure the user that the properties and attributes required by the design drawings and specifications are attained in all production parts. Quality control is the systematic monitoring of manufacturing variables and the control of these variables to maintain the final property variations within the customer's specification.

A critical forging is so designated on the forging drawing and receives very rigid material control. Forgings not designated as critical are subject to less stringent material control. The criticality of a forging is often limited to one location or to a direction of critical stress, such as an axis, because the remaining portions of the forging are employed at

Assuming a rating of 100% for the production attainable with the most forgeable steel, carbon steels gradually decrease in rating from 100% for 0.35% C to 75% for 0.95% C. The ratings for free-machining steels decrease almost proportionally with increasing carbon content, from 98% for C1117 to 93% for C1141, with one exception: B1112 and C1120 have a rating of 100% for attainable production. Ratings for alloy steels range from 94% for those with the least hardenability to 77% for those with the greatest.

Other processing characteristics likely to influence fabricability and finished-part costs should be considered when selecting steel for forgings. Most forgings require some machining, so the machining characteristics of the steel chosen may be a pertinent cost factor. Depending on mechanical property requirements, response to heat treatment may also be expected to affect costs.

Material Control

After completion of a forging design, there remains the responsibility of ensuring and verifying that the delivered forging will have all the properties and characteristics specified on the forging drawing. This responsibility is vested in material control, which

relatively low stress. For such forgings, material control is greater for the portion of the forging under the highest and most critical stress.

Identification. Material control for parts designated as critical includes a system for identification. Typically, each piece is given a serial number, which is recorded and provides a means of identifying the properties of the material, the forging and manufacturing processes, and the results of material-control surveillance. Marking of critical forgings for identification usually includes the part number, serial number, heat number, and forging supplier's symbol. The marking is located where it will remain visible on the part after assembly. If forged-on identification is removed by machining, critical parts are provided with metal tags to maintain identification during shop processing and until the parts are attached to an assembly that is stenciled or otherwise identified.

Routine Production. Material control for the routine production of critical forgings begins by grouping the forgings into lots of a specified maximum size. Results of testing are recorded for the entire lot. Typically, a lot consists of forgings of the same design produced by the same forging producer from the same heat of alloy, heat treated in the same batch, and offered for inspection by (or shipped to) the purchaser at the same time.

Combined Specifications. Material specifications define material properties or requirements. However, they often include one or more sections on processing (such as heat treatment, forging operations, and inspection). Processing specifications may include sections on materials. Therefore, material and process specifications are closely allied and are often combined.

Tests and Test Coupons. Tests contained in the material specifications are intended to provide correlation with, and interpretation of, the behavior of the material in actual use. The dynamic behavior of a full-size structural component can seldom be accurately predicted from simple room-temperature tests on small specimens. Analytical studies coupled with model or full-scale testing can augment simple tests in interpreting the complex behavior of materials.

The types of test specimens and tests specified for quality assurance depend on the conditions imposed on the final component in service. If, for example, a critical forging is to be subjected to large tensile loads, the designer would specify tests to measure fracture toughness and tensile yield strength. For components for elevated-temperature service, tests measuring strength, ductility, and creep at appropriate temperatures would be specified.

The first forging representative of the impression dies, following preliminary trials, is destructively tested for compliance with the specification. After the designer is satisfied that the test results conform to design parameters, the forging design is released for production.

The need to destroy entire forgings for quality assurance during a production run can sometimes be eliminated by designing test coupons, or prolongs (abbreviation for prolongation), into the forging. A prolong is a section of the forging that is removed from the finished forging; it provides test specimens that reflect the forging conditions experienced by the finished part. However, to accurately represent the mechanical properties of the finished part, a prolong must be designed so that it receives the same amount of deformation during forging as the region of the forging it is meant to represent.

The designer must sometimes compromise in selecting the location of test coupons, because of producibility considerations. He must then establish that the test coupons taken from alternative locations will provide data that are meaningful for the intended purpose. Destructive testing permits the designer to determine the degree of correlation between test values measured at critical locations and those measured at the locations to be monitored on each forging in production. Testing of coupons from each production forging should indicate not only whether the forging has exceeded the minimum values assigned to it but also the magnitudes of the values attained at critical locations.

Test Plans. Frequently, specifications are prepared from the results of tests on laboratory specimens, because the cost and time required for full-scale testing are usually prohibitive. Test plans for evaluation of the mechanical properties of two high-strength 9Ni-4Co steels used in aircraft service at temperatures ranging from -45 °C (-50 °F) to more than 205 °C (400 °F) are given in Tables 2 and 3, which illustrate the range and number of tests required for a very extensive type of evaluation.

As indicated in Table 2, test plans for mechanical properties include tension, compression, shear, and bearing strength tests; the effect of grain orientation is evaluated by testing specimens representative of the longitudinal, long-transverse and short-transverse directions, as required. In addition to room-temperature tests, specimens are tested at -80, 150, and 260 °C (-110, 300, and 500 °F). The plan encompasses a total of 285 individual tests.

Table 3 outlines a plan for tests of special properties, including plane-strain fracture toughness, axial fatigue, notched tensile strength, and resistance to stress corrosion. The plan applies to the testing of seven heats of 9Ni-4Co steel at four different temperatures. The tests are designed to evaluate the effects of grain direction; some are conducted on specimens previously exposed under load (275 MPa, or 40 ksi) to temperatures of 150 to 230 °C (300 to 450 °F) for 5000 h. In total, 205 specimens are tested.

Wrought Structure and Ductility. Another aspect of material control ensures that the final forging has undergone sufficient plastic deformation to achieve the wrought structure necessary for development of the mechanical properties on which the design was based. Although some plastic deformation is achieved during the breakdown of a cast ingot into a forging billet, far more is imparted during the closed-die forging process. Material control for high-strength forgings may require determination of the mechanical properties of the forging billet, as well as those of the forging.

A measure of ductility or toughness is determined by measuring the reduction in area obtained in transverse tension test specimens. When corresponding tests are made of transverse and longitudinal specimens taken from forgings heat treated to the same strength level, it is possible to compare the mechanical properties of billet stock and forgings and to estimate the proportion of the final wrought metallurgical structure contributed by each.

Ductility and the Amount of Forging Reduction. A principal objective of material control is to ensure that optimum mechanical properties will be realized in the finished forging. The amount of reduction achieved in forging has a marked effect on ductility, as shown in Fig. 3, which compares ductility in the cast ingot, the wrought (rolled) bar or billet, and the forging. The curves in Fig. 3(a) indicate that when a wrought bar or billet is flat forged in a die, an increase in forging reduction does not affect longitudinal ductility, but does result in a gradual increase in transverse ductility. When a similar bar or billet is upset forged in a die, an increase in forging reduction results in a gradual decrease in axial ductility and a gradual increase in radial ductility.

Fig. 3 Metal flow in forging. Effect of extent and direction of metal flow during forging on ductility. (a) Longitudinal and transverse ductility in flat-forged bars. (b) Axial and radial ductility in upset-forged bars

The ductility of cast ingots varies with chemical compositions, melting practice, and ingot size. The ductility of steel ingots of the same alloy composition also varies, depending on whether they were poured from air-melted or vacuum arc remelted steel. When starting with a large ingot of a particular alloy, it is a times practical to roll portions of the ingot to various billet or bar sizes with varying amounts of forging reduction. The minimum amount of reduction is not standard, but is seldom less than 2:1 (ratio of ingot section area to billet section area). Reduction of steel ingot to billet is usually much greater than 2:1. In contrast, some heat-resisting alloy forgings are forged directly from a cast ingot. Often, it is not feasible to prepare billets for forgings that are so large that they require the entire weight of an ingot.

The amount of forging reduction represented by wrought metallurgical structures is best controlled by observation and testing of macroetch and tension test samples taken from completed forgings. These samples permit exploration of critical areas and, generally, of the entire forging. They are selected from the longitudinal, long-transverse, and short-transverse grain directions, as required. Etch tests permit visual observation of grain flow. Mechanical tests correlate strength and toughness with grain flow.

Grain Flow. Macroetching permits direct observation of grain direction and contour and also serves to detect folds, laps, and reentrant flow. By macroetching suitable specimens, grain flow can be examined in the longitudinal, long-transverse, and short-transverse directions. Macroetching also permits evaluation of complete sections, end-to-end and side-to-side, and a review of uniformity of macrograin size. Figure 4 illustrates grain flow in a representative forged part.

Fig. 4 Flow lines, as shown in a longitudinal section taken through a hook that was forged from 4140 steel

Grain Size and Microconstituents. Metallographic examination, using a microscope, is best suited for examining questionable areas revealed by macroetching, for measuring grain size, and for determining the nature and amount of microconstituents.

Fatigue Strength. Fatigue tests are used in material control under the following conditions and for the following purposes:

- Laboratory testing of small samples for the development or qualification of material
- Laboratory testing of complete components or subassemblies for design development
- Surveillance of components or assemblies in the field to ensure their continuing reliability in service

The laboratory fatigue testing of small samples for the qualification or development of material is done by standard methods. Test specimens are obtained either from mill products or from closed-die forgings, as required. Standard samples are small enough to permit selection from many locations within a forging and to correlate with various directions of grain flow. Testing is generally done at room temperature in air, although testing at higher or lower temperatures and in special atmospheres is feasible.

The application of small-scale laboratory fatigue testing to the analysis of components or assemblies introduces additional variables. One is the effect of surface condition. The curves in Fig. 5(a) demonstrate that the fatigue strength of steel specimens varies markedly, depending on whether the surface is polished, machined, hot rolled, or as-forged. The steel tested was an unidentified wrought low-alloy steel heat treated to 269 to 285 HB, equivalent to a tensile strength of 876 MPa (127 ksi) and a yield strength of 696 MPa (101 ksi). Sample preparation required that the specimens be machined and polished after heat treatment and that rolling or forging precede heat treatment. For a fatigue life of 10^6 cycles, the fatigue limit was 395 MPa (57 ksi) for the ground specimens, 315 MPa (46 ksi) for the machined specimens, 205 MPa (30 ksi) for the as-rolled specimens, and only 150 MPa (22 ksi) for the as-forged specimens.

(a)

(b)

Fig. 5 Effect of surface condition on fatigue limit. (a) Effect of surface condition on fatigue behavior of steels that were hardened and tempered to 269 to 285 HB. (b) Effect of tensile strength level and surface condition of steel on fatigue limit; strengths are given for 10^6 cycle fatigue life.

The curves in Fig. 5(b) apply to steels with tensile strength ranging from 345 to 2070 MPa (50 to 300 ksi) and are approximations from several independent investigations. Sample preparation for as-forged or decarburized specimens at the 965 MPa (140 ksi) tensile strength level include 4140-type steels rough machined from bar stock, heated to approximately 900 °C (1650 °F) in a gas-fired muffle for 20 to 30 min, very lightly swaged from an original 7.47 mm (0.294 in.) diameter to a final diameter of 7.16 mm (0.282 in.), and air cooled. Heat treatment consisted of austenitizing in a salt bath at approximately 830 °C (1525 °F) for 45 min, oil quenching, tempering in air for 1 h at approximately 620 °C (1150 °F), and water quenching. Forging and heat treating produced a surface decarburized to a depth of about 0.064 mm (0.0025 in.). These specimens exhibited a fatigue strength, at 10^6 cycles, of about 310 MPa (45 ksi), compared with 470 MPa (68 ksi) for samples that were not forged but were machined or polished and free of decarburization. Decarburization lowers the strength levels obtained by heat treatment.

Laboratory control of surface condition is difficult to duplicate in the quantity production of forged components. Therefore, the fatigue strength of full-size components varies over a wider range than that of small specimens, because of variations in surface condition.

Fracture Toughness. The brittle fracture of forgings and other components as the result of crack propagation at stress levels considerably below the yield strength of the metal has led to widespread investigation of fracture characteristics and methods of evaluating fracture toughness. Results of these investigations are of major importance to material control, especially with respect to the development of tests for evaluating fracture toughness on which standards for material control can be based.

In the area of laboratory tests and analytical techniques, major emphasis has been placed on the development of dependable methods for evaluating the strength of metals that contain cracks or cracklike defects. Specifically, interest has centered on methods for determining plane-strain fracture toughness. Forged components are evaluated by testing small specimens removed from selected locations on the forging that are representative of the various grain directions. One test procedure comprises the bend testing of notched and fatigue-cracked specimens in a neutral environment (ASTM E 399). The objective of this test is to obtain a lower limiting value of fracture toughness that can be used to estimate the relationship between stress and defect size in a metal under service conditions in which high constraint would be expected.

In the test procedure referred to, a test specimen with a chevron notch is suitably precracked in fatigue. It is then tested in a bend test fixture provided with support rolls that rotate and move apart slightly to permit rolling contact and virtually eliminate the friction effect. The specimen is subjected to three-point bending, and the imposed load versus displacement change across the notch is recorded on an autographic recorder. Fracture toughness is rated by a calculated parameter, the critical stress intensity.

End-Grain Exposure. Lowered resistance to stress-corrosion cracking in the long-transverse and short-transverse directions is related to end-grain exposure. A long, narrow test specimen sectioned so that the grain is parallel to the longitudinal axis of the specimen has no exposed end grain, except at the extreme ends, which are not subjected to loading. In contrast, a corresponding specimen cut in the transverse direction has end-grain exposure at all points along its length. End grain is especially pronounced in the short-transverse direction on die forgings designed with a flash line. Consequently, forged components designed to reduce or eliminate end grain have better resistance to stress-corrosion cracking.

Residual Stress. The sustained tensile stress at the surface of a forging that contributes to stress-corrosion cracking is the total of applied and residual stresses. When the residual stress constitutes a significant percentage of the total stress, it should be reduced or eliminated.

Common sources of residual tensile stresses include quenching, machining, and poor fit in assembly. Each can be suitably modified to reduce or eliminate tensile stresses, especially those present in an exposed surface. For example, drastic quenching places the surface of a heat-treatable alloy in a state of compression and the core in a state of tension. Furthermore, the compressed surface may be entirely removed during rough machining, exposing the tension-stressed core material. This hazard can be avoided by quenching after, rather than before, rough machining. In some applications, a surface in tension is placed in compression by shot peening.

Hydrogen-stress cracking occurs without corrosion; therefore, its initiation is not confined to exterior surfaces in contact with a corrosive medium. It can start at any suitable nucleus, such as an inclusion or void, as well as at a surface notch or other irregularity. Hydrogen-stress cracking at the interior is described as hydrogen embrittlement or hydrogen flaking.

Hydrogen-stress cracking has been observed, studied, and brought under control in most high-strength steels. The modern practice of vacuum melting can reduce residual hydrogen to negligible amounts. A hydrogen content of 3 to 6 ppm in an air-melted steel can be readily lowered to 0.6 to 1 ppm by vacuum arc remelting.

Provided that the initial hydrogen content of the steel is acceptably low, material control procedures must ensure that hydrogen pickup is avoided in all subsequent processing, including forging, heat treating, hot salt bath descaling, pickling, and plating. During forging, steels develop a surface scale and a decarburized surface layer, both of which are subsequently removed by gritblasting and machining. Unless the steel is acid pickled, there is no possibility of hydrogen pickup.

Many of the critical parts made from steel forgings are protected by a coating of cadmium. Steel parts heat treated to strength levels higher than 1655 MPa (240 ksi) are especially sensitive to hydrogen pickup; if they are coated with cadmium, the coating is deposited in vacuum. Parts heat treated to strength levels lower than 1655 MPa (240 ksi) can be cadmium plated electrolytically, provided that a titanium-containing plating bath is used and the parts are subsequently baked at about 190 °C (375 °F) for 12 h.

Mechanical Properties

A major advantage of shaping metal parts by rolling, forging, or extrusion stems from the opportunities such processes offer the designer with respect to the control of grain flow. The strength of these and similar wrought products is almost always greatest in the longitudinal direction (or equivalent) of grain flow, and the maximum load-carrying ability in the finished part is attained by providing a grain-flow pattern parallel to the direction of the major applied service loads when, in addition, sound, dense, good-quality metal of sufficiently fine grain size has been produced throughout.

Grain Flow and Anisotropy. Metal that is rolled, forged, or extruded develops and retains a fiberlike grain structure aligned in the principal direction of working. This characteristic becomes visible on external and sectional surfaces of wrought products when the surfaces are suitably prepared and etched. The fibers are the result of elongation of the microstructural constituents of the metal in the direction of working. Therefore, the phrase "direction of grain flow" is commonly used to describe the dominant direction of these fibers within wrought metal products.

In wrought metal, the direction of grain flow is also evidenced by measurements of mechanical properties. Strength and ductility are almost always greater in the direction parallel to that of working. The characteristic of exhibiting different strength and ductility values with respect to the direction of working is referred to as mechanical anisotropy and is exploited in the design of wrought products. Although the best properties in wrought metals are most frequently the longitudinal (or equivalent), properties in other directions may yet be superior to those in products not wrought, that is, in cast ingots or in forging stock taken from a lightly worked ingot.

The square rolled section shown schematically in Fig. 6(a) is anisotropic with respect to the average mechanical properties of test bars positioned as shown. The average mechanical properties of longitudinal bar 1 are superior to those of transverse bars 2 and 3. Mechanical properties are equivalent for bars 2 and 3 because the section is square, which implies equal reduction in section in both transverse directions.

Fig. 6 Anisotropy and mechanical properties in forgings. Schematic views of sections from (a) square rolled stock, (b) rectangular rolled stock, (c) a cylindrical extruded section, and (d) a ring-rolled section, illustrating the effect of section configuration or forging process, or both, on the longitudinal direction in a forging

Mechanical anisotropy is also found in rectangular sections (Fig. 6b), in cylinders (Fig. 6c), and in rolled rings (Fig. 6d). Again, the best strength properties are, on the average, those of the longitudinal, as in test bar 1. Flat rolling of a section such as Fig. 6(a) to a rectangular section such as Fig. 6(b) enhances the average long-transverse properties of test bar 4 when compared with the short-transverse properties of test bar 5. Thus, such rectangular sections exhibit anisotropy among all three principal directions--longitudinal, long transverse, and short transverse. A design that employs a rectangular section such as Fig. 6(b) involves the properties in all these directions, not just the longitudinal. Thus, the longitudinal, long-transverse, and short-transverse service loads of rectangular sections are analyzed separately. The same concept can be applied to cylinders, whether extruded or rolled; longitudinal direction changes with the forging process used, as indicated in Fig. 6(c) and 6(d).

Anisotropy in High-Strength Steel. Although all wrought metals are mechanically anisotropic, the effects of anisotropy on mechanical properties vary among different metals and alloys. For example, a vacuum-melted steel of a given composition is generally less mechanically anisotropic than a conventionally killed, air-melted steel of the same composition. Response to etching to reveal the grain flow characteristic of anisotropy also varies. Metals with poor corrosion resistance are readily etched, while those with good corrosion resistance require more corrosive etchants and extended etching times to reveal grain flow.

In general, fatigue properties are markedly affected by the relation of flow-line direction to direction of stresses from applied loads: When flow lines are perpendicular to load stresses, a stress-raising effect is produced.

Table 4 gives test results from tensile specimens for two different kinds of alloy steel taken from a heat-treated forging. In another study of these directional effects on 4340 and 4330 modified steel, at different strength levels, large closed-die forgings approximately 305 mm (12 in.) in diameter and 1.2 m (4 ft) in length were bored to leave a wall thickness of 28.5 to 38 mm ($1\frac{1}{8}$ to $1\frac{1}{2}$ in.) and then heat treated. These forgings had been formed from a 380 mm (15 in.) square billet by a 22 kN (5000 lbf) blacksmith hammer, a 110 kN (25,000 lbf) blocking hammer, and a 160 kN (35,000 lbf) finishing hammer.

Table 4 Effect of orientation of test specimen on mechanical properties of steel forgings

Specimen orientation ^(a)	Yield strength		Tensile strength		Elongation, in 50 mm (2 in.), %	Reduction in area, %	Hardness, HB
	MPa	ksi	MPa	ksi			
Steel 5046							
Longitudinal	585	85	820	119	25.5	64.1	255

Steel 4340							
Longitudinal	1005	146	1095	159	19.0	54.5	341
Diagonal	1000	145	1090	158	17.5	49.3	331
Transverse	1000	145	1095	159	13.5	29.9	341

(a) Specimen orientation described in illustration

Three sets of specimens were cut, as indicated in Table 5. One set was longitudinal, or parallel to the forging axis; another was transverse, or normal to the forging axis away from the parting line; and the third set was vertical across the parting line, with the critical section in the center of the parting-line region. The results of tests summarized in Table 5 show differences in properties resulting from orientation. Differences can be expected in all forgings regardless of the steel used or its strength after heat treatment.

Table 5 Effect of location and orientation on mechanical properties of specimens cut from production forgings

All values shown are averages. A total of 7 tensile, 10 notch-tensile, 15 impact, and 5 bend specimens were tested for each steel. Standard 12.8 mm (0.505 in.) round tensile specimens were used. Notch-tensile specimens of 7.6 mm (0.300 in.) nominal outside diameter had a circumferential 60° V-notch that removed 50% of the section area. The root radius was less than 0.025 mm (0.001 in.). Bend specimens were 11.11 mm (0.4375 in.) in diameter by 143 mm ($5\frac{5}{8}$ in.) long. The data were obtained with the restricted-bend method, in which the specimen is supported at each end and the load is applied at the center of the specimen. Locations of specimens were longitudinal, transverse, and transverse to parting line (see cut).

A total of 7 tensile, 10 notch-tensile, 15 impact, and 5 bend specimens were tested for each steel in each orientation. Standard 12.83 mm (0.505 in.) round tensile specimens were used. Notch-tensile specimens of 7.62 mm (0.300 in.) nominal outside diameter had a circumferential 60° V-notch that removed 50% of the section area. The root radius of the notch was less than 0.025 mm (0.001 in.). Bend specimens 11.1 mm (0.438 in.) in diameter were 143 mm ($5\frac{5}{8}$ in.) long. The restricted-bend method was used; the specimen was supported at each end and centrally loaded.

Design Stress Calculations

Example 1: Redesign of a Forged Manual Gear-Shift Lever Mechanism to Overcome Unacceptable Fatigue Failure of Original Forging.

In a hand-operated gear-shift lever mechanism, field performance was generally satisfactory, but some fatigue failures occurred in the 3.18 mm ($\frac{1}{8}$ in.) radius shown in Fig. 7. The lever is pivoted in a ball socket, and the maximum load transmitted at end A is 1.8 kN (400 lbf). The steel is 1049 hardened to 269 to 285 HB, with properties as given in Table 6.

Fig. 7 Original and revised lever designs showing plot of stresses in the original and redesigned part. Dimensions given in millimeters

As a simple lever, the stress at section A would be calculated as follows:

$$\begin{aligned}\text{Bending moment} &= M \\ &= (\text{force at A})(\text{lever arm}) \\ &= (400 \text{ lbf})(7 \text{ in.}) \\ &= 2800 \text{ lbf} \cdot \text{in. or } 315 \text{ N} \cdot \text{m}\end{aligned}\tag{Eq 1}$$

$$\text{Stress} = \frac{\text{Bending moment}}{\text{Section modulus}} = 262 \text{ Mpa or } 38 \text{ Ksi}\tag{Eq 2}$$

Because an abrupt change in size occurs at section A, a stress concentration factor must be applied. This value is obtained from Fig. 8. Values applied to the curves are as follows: from the dimensions in Fig. 7, $r = 3.18 \text{ mm}$ (0.125 in.), $d = 22.2 \text{ mm}$ (0.875 in.), and $h = 4.75 \text{ mm}$ (0.187 in.). Therefore:

$$\frac{r}{d} = \frac{3.18}{22.2} = 0.143\tag{Eq 3}$$

and

$$\frac{h}{r} = \frac{4.75}{3.18} = 1.5\tag{Eq 4}$$

The stress concentration factor for these values, or r/d and h/r , is $K_f = 1.52$, from Fig. 8. Therefore, the calculated mean stress would be $1.52 \times 262 \text{ MPa} = 400 \text{ MPa}$ (or $1.52 \times 38 \text{ ksi} = 58 \text{ ksi}$). This stress is well below the yield strength (696 MPa, or 101 ksi). However, the occurrence of failures under service conditions suggested fatigue as the mode of failure.

Fig. 8 Stress concentration factor obtained in bending a quenched and tempered steel shaft having a circular fillet

To investigate actual stresses, a strain gage was installed in the radius, and observations made during operation revealed stresses from 275 to 345 MPa (40 to 50 ksi). However, when gears were clashed, transient load impulses as long as $2\frac{1}{2}$ s in duration resulted in stress as high as 620 MPa (90 ksi) at a frequency of 80 Hz. Therefore, about 200 stress reversals could occur several times during each hour the machine was in operation. This condition explains the possibility of the

occurrence of 10^6 cycles in a few thousand hours of actual operation. It was necessary, therefore, to consider a means of reducing the stress because of fatigue.

A draftsman's layout of the related parts revealed that the diameter could be increased to 25 mm (1 in.) and the radius to 4.75 mm (0.187 in.). Also, instead of the as-forged surface, it was expedient to machine the radius as shown in the following stress analysis (Fig. 7).

In Eq 2, bending moment is unchanged, but the section modulus changes because of increased diameter. Then, the stress after redesigning is:

$$Stress = \frac{Bending\ moment}{Section\ modulus} = 175Mpa\ or\ 25Ksi \quad (Eq\ 5)$$

In using Fig. 8:

$$\frac{r}{d} = \frac{4.75}{25} = 0.187 \quad (Eq\ 6)$$

and

$$\frac{h}{r} = \frac{4.75}{4.75} = 1 \quad (Eq\ 7)$$

Therefore, the stress concentration factor with the 4.75 mm (0.187 in.) radius would be reduced slightly, to 1.43, and the calculated mean stress after redesigning would be $1.43 \times 175\ MPa = 250\ MPa$ (or $1.43 \times 25\ ksi = 36\ ksi$).

Life Expectancy. The foregoing computations have shown the calculated stresses for two different configurations at section A. It was determined experimentally that peak stresses of 620 MPa (90 ksi) were observed in the original condition. The peak stresses with the enlarged diameter and radius are reduced proportionally to the calculated stresses. Therefore, the new peak stress would be:

$$\frac{250}{400}(620) = 390Mpa\ or\ 57Ksi \quad (Eq\ 8)$$

The following discussion compares the effect of these maximum stresses on the life expectancy of the part.

In Fig. 5, the values for completely reversed cycles of stress for steel at a hardness range of 269 to 285 HB are plotted against life in cycles for as-forged, hot-rolled, machined, and ground surfaces. The problem at hand concerns as-forged versus machined surfaces. The forged surface would be decarburized and subject to the usual surface defects. At 10^6 cycles, as before, the allowable stress for a forged surface as read from Fig. 5 is 150 MPa (22 ksi), while for the machined surface it is 315 MPa (46 ksi)--both considerably less than the yield strength (690 MPa, or 100 ksi).

Figure 9 shows the relationship between maximum and mean stress for forged and machined surfaces of the example part. At zero mean working stress (complete reversal), the values are the same as in Fig. 5 for 10^6 cycles. At the point in the upper right-hand corner of Fig. 9 where mean and maximum stresses are equal, both stresses are equal to the tensile strength of the steel; therefore, the load is static.

Fig. 9 Maximum stress versus mean working stress for steel with forged and machined surfaces. See Example 1 in text.

In Fig. 9, the mean working stress of the original forging is represented by line 1, drawn from mean stress 395 MPa (57 ksi) vertically to its intersection with line 3 to predict a maximum stress of 475 MPa (69 ksi) for the forged surface, and drawn to its intersection with line 4 to predict a maximum stress of 565 MPa (82 ksi) for the machined surface. The stress of 565 MPa (82 ksi) is nearly equal to the maximum observed by strain gage analysis and therefore is indicative of failure. The vertical line 2 in Fig. 9 represents stresses in the redesigned forging for which the mean stress previously calculated is 250 MPa (36 ksi). The values on the appropriate vertical line 2 of Fig. 9 show maximum working stresses of 360 MPa (52 ksi) for the forged surface and 475 MPa (69 ksi) for the machined.

The as-forged surface at 360 MPa (52 ksi) maximum working stress would not ensure satisfactory life, because the recalculated maximum stress is 390 MPa (57 ksi). However, the machined surface with a maximum working stress of 475 MPa (69 ksi) gives a safe margin above the 390 MPa (57 ksi) requirement for design stress. Interpreting these values, the forged surface should have a life expectancy of 10^6 cycles of stress. However, because the load cycle was somewhat uncertain, the machined radius was chosen to obtain a greater margin of safety. The foregoing discussion is diagrammed in Fig. 7 to show the values of calculated mean, peak, and minimum stresses in the problem on the original and the redesigned levers. Redesigning eliminated the failures.

Fundamentals of Hammer and Press Forgings

Many small forgings are made in a die that has successive cavities to preshape the stock progressively into its final shape in the last, or finish, cavity. Dies for large forgings are usually made to perform one operation at a time. The upper half of the die, having the deeper and more intricate cavity, is keyed or dovetailed into the hammer or press ram. The lower half is keyed to the sow block or bed of the hammer or press in precise alignment with the upper die. After being heated, the forging stock is placed in one cavity after another and is thus forged progressively to the final shape.

The parting line is the plane along the periphery of the forging where the striking faces of the upper and lower dies come together. Usually, the die has a gutter or recess just outside of the parting line to receive overflow metal or flash forced out between the two dies in the finish cavity (Fig. 10). More complex forgings may have other parting lines around holes and other contours within the forging that may or may not be in the same plane as the outer parting line.

Fig. 10 Two stages of metal flow in forging. Top diagram shows limitations on height of ribs above and below the parting line.

For the greatest economy, the outer parting line should be in a single plane. When it must be along a contour, either step or locked dies (that is, dies with mating faces that lie in more than one plane) may be necessary to equalize thrust, as shown in Fig. 11. This may increase costs as much as 20%, because of the increased cost of dies and cost increases from processing difficulties in forging and trimming. Sharp steps or drops in the parting line should be limited to about 15° from the vertical in small parts and 25° in large forgings to prevent a tearing instead of a cutting action in trimming off the flash. Locked dies can sometimes be avoided by locating the parting line as shown in Fig. 12(b).

Fig. 11 Locked or stepped dies used to equalize thrust

Fig. 12 Orientation of a forging in the die to avoid counterlocked dies and to eliminate draft. Workpiece forged with (a) and without (b) lock in die

The specification of optional parting lines on forgings to be made in different shops allows these lines to vary from shop to shop. Unless the draft has been removed, this variation may cause difficulties in locating forgings when they are being chucked for subsequent machining. However, shearing the draft is not always an adequate remedy if trimming angles vary. Forgings made in different shops are likely to be more consistent in quality and to have less variation in shape when a definite parting line is specified.

Draft on the sides of a forging is an angle or taper necessary for releasing the forging from the die and is desirable for long die life and economical production. Draft requirements vary with the shape and size of the forging. The effect of part size on the amount of metal needed for draft is illustrated by Fig. 13.

Fig. 13 Effect of part size on the amount of metal needed for draft in a forging

Inside draft is draft on surfaces that tightens on the die as the forging shrinks during cooling; examples are cavities such as narrow grooves or pockets. Outside draft is draft on surfaces such as ribs or bosses that shrink away from the die during cooling. Both are illustrated in Fig. 14, which shows inside draft to be greater than outside draft--the usual relation. Recommended draft angles and tolerances are given in Table 7.

Table 7 Draft and draft tolerances for steel forgings

Height or depth of draft		Commercial standard		Special standard	
mm	in.	Draft, degree	Tolerance ^(a) , degree	Draft, degree	Tolerance ^(a) , degree
Outside draft					
6.35-12.7	$\frac{1}{4} - \frac{1}{2}$	3	+2
19-25	$\frac{3}{4} - 1$	5	+3
>12.7-25	$>\frac{1}{2} - 1$	5	+2
>25-76	>1-3	7	+3	5	+3
>76	>3	7	+4	7	+3
Inside draft					
6.35-25.4	$\frac{1}{4} - 1$	7	+3	5	+3
>25.4	>1	10	+3	10	+3

(a) The minus tolerance is zero.

Fig. 14 Definition of inside and outside draft and limitations on the depth of the cavities between the ribs. Typically, inside-draft angles exceed outside-draft angles.

Increased draft, called blend draft or matched draft, may be needed on a side that is not very deep below the parting line in order to blend with a side of the forging of greater height above the parting line, as shown in Fig. 15. Increased draft is sometimes desirable or required in locked dies in order to strengthen the dies or trimmer so as to reduce breakage and cost. This can often be anticipated by sketching the die needed to shape a given forging. Cylindrical, spherical, square, rectangular, and some irregular sections can be forged without draft when the parting line is specified as shown in Fig. 16, but with some additional risk of breakage of dies. Other parts, such as the ends of cylinders, can be forged in locked dies at an angle so as to avoid draft on the ends.

Fig. 15 Normal draft and blend draft in a forging

Fig. 16 Selection of parting lines to eliminate draft in (a) cylindrical, (b) square, and (c) tube-shaped forgings

Ribs and Bosses. Forgings that have ribs or bosses at or near the maximum heights recommended in Fig. 10 are usually forged at higher-than-normal temperatures (1230 to 1260 °C, or 2250 to 2300 °F) to ensure flow of the metal into the die cavities. Ribs are more readily formed in the upper die, where the temperature is higher; the lower die extracts heat from the forging, which is in continuous contact with it. The ribs formed by the upper die have better surface quality than those in the lower die, because scale left by the part is more easily removed.

The maximum height of a rib depends on its width at the base and on blocking operations that preshape the stock. Fillets of minimum size cannot be used at the base of a rib of maximum height if the rib is to be sound and completely filled. Twice the minimum fillet size should be used, a full radius is preferable at the crest of the rib, and draft should be increased if possible.

Fillets and Radii. In forging, some radii wear and grow greater; others become sharper under the combined effects of the pressure of the press or of repeated hammer blows and abrasion. Radii that are too small give the forge die a shearing action and develop high resistance to the flow of the metal, thus increasing die wear and reducing its life. Radii should be as large as the design will permit. Sharp radii in a forging die set up strains that cause the die to check, thus reducing die life and increasing cost. Very little material can be saved by producing a design that includes sharp internal (fillet) radii.

The effects of small and large radii are illustrated in Fig. 10, which shows a forging during two stages of the operation. In small steel forgings (<0.9 kg, or 2 lb), 3.2 mm ($\frac{1}{8}$ in.) radii in fillets are considered the absolute minimum. Common practice is to make the fillet radii twice the size of the corner radii. These radii increase in proportion to the size and weight of the forgings, as shown in Fig. 17. For steel forgings of average size (1.4 to 3.6 kg, or 3 to 8 lb), 6.4 mm ($\frac{1}{4}$ in.) fillet radii are normal. Recommended fillet and corner radii for various heights of rib or boss are given in Fig. 18.

Fig. 17 Minimum fillet and corner radii for steel forgings

Fig. 18 Recommended fillet and corner radii in relation to height of rib or boss

completed. If the web gets cold enough in forging to look black, it prevents the part from being brought down to size. Figure 19 shows the limiting minimum web dimension as a function of web size. The minimums shown are generally accomplished on various metals with more or less difficulty--particularly in a problem forging that, in a forging hammer, requires more than a few blows for completion. Many web thicknesses that fall into the band between the two curves can be made only with difficulty and at extra cost. Some that fall below the curve are regularly produced, while the web thicknesses that fall above the upper curve are almost always made without extra cost in forgings that can be completed rapidly. When a web thinner than recommended is required, some advantage may be gained by tapering it 5 to 8° toward the thinnest section, at the center, but the average minimum thickness of the web must be retained to meet strength requirements.

Fig. 19 Recommended minimum web thickness in relation to web dimensions

Holes and Cavities. Holes should not obstruct the natural flow of the metal in the forging operation. If cavities lie perpendicular to the direction of metal flow, it may be necessary to add breakdown or blocking operations on the forging billet before it is placed in the dies for forging. Such operations add cost and so must be justified economically. In almost all cases in which a hole is to be punched, a forced cavity is provided to displace the metal in order to relieve the work load of the punch in the later operation. Holes and cavities should not be higher or deeper than the base of the widest cross section when normal fillets and radii are used. If a full radius or a hemispherical shape is allowed at the bottom of a cavity, the maximum depth of the cavity may be $1\frac{1}{2}$ times the width (diameter), as shown in Fig. 14.

On shallow cavities, a draft angle of 7° and the required normal radii can be used. On cavities of maximum depth, the draft should be increased to 10 to 12°.

Minimum Web Thickness. The web in a forging is limited to the thickness at which it gets too cold before forging is

Lightening Holes in Webs. Holes are not always desirable as a means of reducing weight, because of the effect on the strength of the part and stress concentration. Lightening holes are almost always produced by an added operation, and the expense involved is often unjustified. These holes should be used only in neutral or low-stress areas or to reduce cooling cracks and warpage caused by uneven cooling. Holes should be kept away from edges and provided with a strengthening bead to reduce stress concentration, as shown in Fig. 20. A hole near the edge of a forging usually leaves inadequate material in the highly stressed area around the hole, thus increasing the possibility of crack nucleation and severe distortion.

Fig. 20 Lightening holes located in the webs of a forging

such as mismatch, die wear, and length, should be added to the allowance for machining plus machined dimensions. On average, the tolerances listed in Tables 8 and 9 conform to the full process tolerance of actual production parts and yield more than 99% acceptance of any dimension specified from Tables 8 and 9. In particular, as shown in Table 10, instances may be found of precise accuracy or rarely as much as $\pm 50\%$ error in the tolerances recommended in Table 9. The values in Table 10 represent the product of a die for one run and not the full range of product between successive resinkings of the die.

Table 8 Recommended commercial tolerances on length and location

Maximum length of forging		Tolerance on length or location	
mm	in.	mm	in.
150	6	+1.19, -0.79	+0.047, -0.031
380	15	+1.57, -1.19	+0.062, -0.047
610	24	+3.18, -1.57	+0.125, -0.062
910	36	+3.18, -1.57	+0.125, -0.062
1220	48	+3.18, -3.18	+0.125, -0.125
1520	60	+4.75, -3.18	+0.187, -0.125

Scale Control. The reduction of scale formation and the removal of scale during the forging process are important considerations in meeting design requirements economically. Gas- and oil-fueled preheat furnaces should be adjusted to produce a reducing atmosphere and thus minimize the creation of scale. Induction heating can be a useful alternative to fossil fuel furnaces. In some cases, the weight loss due to scaling can be reduced from 2 to 3% for gas or oil furnaces to 0.2% for induction heating.

Tolerances

Forging tolerances, based on area and weight, that represent good commercial practice are listed in Tables 8 and 9. These tolerances apply to the dimensions shown in the illustration in Table 8. In using Tables 8 and 9 to determine the size of the forging, the related tolerances,

1830	72	+5.56, -3.18	+0.219, -0.125

(a) The illustration in Table 8 shows locations of thickness and mismatch.

Table 10 Comparison of quality-control data with recommended tolerances for seven production forgings

Values represent the product of a die for one run and not the full range of product between successive resinkings of the die. All tolerances are plus; negative tolerances, zero. Plus signs in the last column indicate that the recommended tolerance is conservative compared with production experience. σ represents standard deviation in distribution of measured dimensions.

Part	Recommended tolerance (from Table 9)		Range of observed variation in length for specific quality-control limits				Difference between tolerance (from Table 9) and 6σ control limit	
			4σ		6σ			
	mm	in.	mm	in.	mm	in.	mm	in.
A	2.39	0.094	1.07	0.042	1.60	0.063	+0.79	+0.031
B	2.39	0.094	1.30	0.051	1.93	0.076	+0.46	+0.018
C	2.39	0.094	1.52	0.060	2.29	0.090	+0.10	+0.004

E	3.18	0.125	2.06	0.081	3.10	0.122	+0.08	+0.003
F	3.18	0.125	2.64	0.104	4.22	0.166	-1.04	-0.041
G	3.18	0.125	2.82	0.111	4.22	0.166	-1.04	-0.041

Shift or mismatch tolerance allows for the misalignment of dies during forging, as shown in Fig. 21. All angular or flat surfaces of the die will erode or wear away and increase the volume of the forging, depending on the extent to which the forged metal flows over them. This increase is called spread, or die wear, and it must be included in the forging dimensions.

Fig. 21 Application of tolerances and allowances to forgings. The dimensions are not to scale. a, finish machined; b, machine allowance; c draft allowance; d, die wear tolerance; e, shrink or, length tolerance; f, mismatch allowance

The characteristics of die wear are illustrated in Fig. 22. The part represented was made of 4140 steel, using ten blows in an 11 kN (2500 lbf) board hammer. Tolerances were commercial standard, and the part was later coined to a thickness tolerance of +0.25 mm, -0.000 mm (+0.010 in., -0.000 in.). The die block, 255 by 455 by 455 mm (10 by 18 by 18 in.), was hardened to 42 HRC. After 30,000 forgings had been produced, the die wore as indicated and the dies were resunk.

Fig. 22 Schematic showing extent of die wear in a die block hardened to 42 HRC. The block was evaluated for die wear after producing 30,000 forgings of 4140 steel at a rate of 10 blows/workpiece with an 11 kN (2500 lbf) hammer.

A range of tolerance is given for mismatch in Table 9. The higher values are to be added to tolerances for forgings that need locked dies or involved side thrust on the dies during forging. On forgings heavier than 23 kg (50 lb), it is sometimes necessary to grind out mismatch defects up to 3.2 mm ($\frac{1}{8}$ in.) maximum.

Length tolerance in Table 8 refers to variations in shrinkage that occur when forgings are finished at different temperatures. Length tolerance should be applied to overall lengths of forgings as well as to the locations of bosses, ribs, and holes.

Areas of a forging can be coined to hold closer tolerances, provided the metal is free to flow into an adjacent open area of the part. Under these circumstances, the tolerances shown in Fig. 23 can be held in production without difficulty. Over a hot-sheared surface, the coining operation will bring the high points of the serrations within tolerance without removing all the depressions.

Fig. 23 Tolerances for coining unconfined areas of forgings

On average, Table 9 represents full process tolerance. Figure 24 indicates the relationship of the number of acceptable parts to the process tolerance. In application, the full process tolerance must be derived from the process capability, the full value of which is represented on the chart as full process tolerance within which 100% (theoretically 99.7%) acceptability will result.

Fig. 24 Relationship of percentage of acceptable parts to process tolerance specified on a dimension

For a given process and tolerance, if the designer chooses to narrow the tolerance to two-thirds of its full value, the acceptability will be reduced to 95%. Similarly, a reduction to one-third of the full tolerance would result in acceptability of 68%. Such reduction in tolerance incurs added expense because of the costs of rejected standard forgings and of 100% inspection to separate acceptable from rejected parts. Although it is possible to control the forging process more closely so as to increase the percentage of acceptable parts, the added expense will also increase the cost of the parts.

Flash is trimmed in a press with a trimming die shaped to suit the plan view, outline, and side view contour of the parting line. The forging can be trimmed with a stated amount of burr or flash left around the periphery at the parting line. It can also be trimmed flush to the side face of the forging, or some of the draft can be trimmed off, provided the serrations or score marks left by the shearing operation are not an objectionable feature. In most commercial forgings, some draft is sheared away.

Trimming Tolerance. When the trim must cut through the flash only and leave the side of the forging untouched, it is necessary to use a trim dimension that includes burr tolerance, mismatch, draft tolerance, and die wear plus shrink tolerance. When it is satisfactory to trim draft partially, a closer trim tolerance can be held. Burr tolerance, listed in Table 11, applies to the amount of flash that should remain between the side of the forging at the parting line and the outside edge of the trim cut.

Table 11 Tolerance on burr for steel forgings

Weight		Trim size ^(a)		Tolerance	
kg	lb	mm	in.	mm	in.
0.45	1	50	2	+0.79, -0.000	+0.031, -0.000
4.5	10	150	6	+1.57, -0.000	+0.062, -0.000
11	25	200	8	+3.18, -0.000	+0.125, -0.000
45	100	625	25	+6.35, -0.000	+0.250, -0.000

(a) The trim size refers to the greatest distance across the forging at the trim line.

Draft tolerance depends of the height of the face having the draft and applies to the dimension across the forging at the parting line. Draft tolerance (plus) is listed in Table 12 for six different heights of the draft face on forgings.

Table 12 Draft increment of trim tolerance for steel forgings

Height of draft face		Tolerance	
mm	in.	mm	in.
6.35	$\frac{1}{4}$	+0.38, -0.00	+0.015, -0.000
12.70	$\frac{1}{2}$	+0.51, -0.00	+0.020, -0.000
25	1	+0.9, -0.00	+0.035, -0.000
51	2	+1.5, -0.00	+0.060, -0.000
127	5	+4.5, -0.00	+0.175, -0.000
254	10	+8.9, -0.00	+0.350, -0.000

Die wear tolerance allows for an economical life of tools by providing for acceptability of parts after the die has made a quantity of pieces. The tolerance to be added to trimming and draft tolerances to allow for die wear are given in Table 13. The fourth part of the total tolerance is 0.003 mm/mm (0.003 in./in.) of the greatest dimension across the forging at the trim line, to be added as shrink tolerance.

Table 13 Die wear increment of the trim tolerance for steel forgings

Weight		Trim size ^(a)		Tolerance	
kg	lb	mm	in.	mm	in.
0.45	1	50	2	+0.79, -0.00	+0.031, -0.000
4.5	10	150	6	+1.19, -0.00	+0.047, -0.000
11	25	200	8	+1.57, -0.00	+0.062, -0.000

45	100	625	25	+3.18, -0.00	+0.125, -0.000
----	-----	-----	----	--------------	----------------

(a) The trim size refers to the greatest distance across the forging at the trim line.

Example 2: Trim Tolerance as Summation of Four Individual Tolerances.

The use of Tables 9 and 11, 12, and 13 may be illustrated by the following example. Assume a 2.3 kg (5 lb) forging 127 mm (5 in.) high and 127 mm (5 in.) across at the minimum shearing dimension. The tolerance is the sum of 1.1 mm (0.045 in.) burr tolerance, 4.4 mm (0.175 in.) draft tolerance, 1.0 mm (0.040 in.) die wear tolerance, and 0.38 mm (0.015 in.) shrink tolerance, which equals 7.0 mm (0.275 in.) trim tolerance. Thus, 134.0 mm (5.275 in.) is the largest dimension allowed for trimming when the side of the forging must not be cut, and 127.0 mm (5.000 in.) is the smallest dimension to be allowed. This tolerance is most economical, but in many forgings the tolerance can be held as close as that shown in Table 3 by close control or extra operations.

Hot shearing removes the draft from forgings with a vertical cut that improves dimensional accuracy and leaves a serrated surface. This characteristic surface and accuracy represent an economical preparation for machining, broaching, coining, and accurate chucking in standard chucks. The surface is a substitute for rough machining or flame cutting.

The least expensive trimming operation on forgings is the cold trimming of small parts made from carbon steel of less than 0.50% C or from alloy steel of less than 0.30% C. However, to hot shear off about two-thirds of the draft is economical because the special locating tools required for shearing off all the draft are not needed. The holes and outside of a forging can be sheared in one operation with a combination trimmer and punch for parts where the sheared burr of the holes and the outside are not required to be on opposite sides of the forging.

The force of the shearing operation results in a rounded contour, called pull down, where the shear begins, and in sharp burr edges on the opposite side of the forging where the shear ends, as shown in Fig. 25. The trimming and piercing forces are sometimes great enough to crush or distort the forging. For example, the force of piercing a hole in a thin-wall hub may expand the outside dimension if there is no outer flange to support it. If the wall has a flange around the outside, the piercing forces may crush the lower ends of the hub.

Fig. 25 Pull-down effect in hot shearing, a commonly specified operation for removing the draft from forgings. Pull-down effect, which results from the force of the shearing operation, marks the point where shear begins; burr, where shear ends.

Piercing. Expansion may occur in hot piercing a hole in a cylindrical piece when the unsupported outside wall is 1.5 times the diameter of the pierced hole. Parts with an outside diameter only 1.2 times the diameter of the pierced hole will be distorted. In some parts in which the outer surface is sheared in the same operation that pierces the hole, an outside diameter 1.4 times the diameter of the hole can sometimes be used with good results. Generally, however, 1.57 mm

(0.062 in.) should be added to the end of the piece for such parts to allow for crushing of the ends if the ratio of outside diameter to inside diameter is less than 1.5. If the ratio is about 1.6, an allowance of 0.81 mm (0.032 in.) is satisfactory; for ratios of outside to inside diameter greater than 1.75, this allowance is seldom necessary. All of the above ratios refer to dimensions after piercing.

Broaching Allowance. The amount of metal to be removed in broaching a hole in a forging can be controlled economically by hot piercing the hole to close tolerances or, less economically, by machining the hole before broaching. Figure 26 is a graph of the forging stock and tolerances to be allowed in a hole that is to be broached after hot piercing. In using Fig. 26, the allowance value at a given diameter is subtracted from the minimum broach diameter. This is the high limit for the size of the hot-pierced hole. The hole dimension is then specified as the high limit with a tolerance of plus zero, minus the tolerance read from Fig. 26.

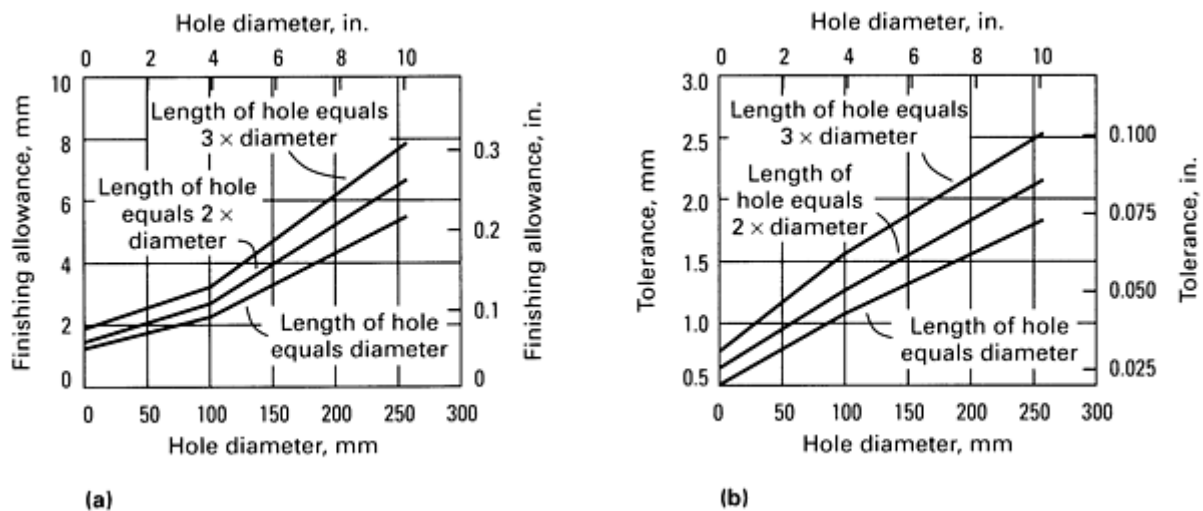

Fig. 26 Allowances (a) and tolerances (b) for hot-pierced holes that are to be broached

Allowance for Machining

Surfaces that are to be machined must be forged oversize externally and undersize internally by an amount equal to the sum of applicable tolerances and machining allowance, as shown in Fig. 27. On machined surfaces parallel to the parting line, the stock allowance is affected by the tolerances for thickness and straightness. Machined surfaces perpendicular or nearly perpendicular to the parting plane are affected by the length tolerances, straightness, and mismatch tolerances. The minimum machining allowance, set somewhat arbitrarily at 1.52 mm (0.060 in.) on small forgings and as high as 6.35 mm (0.250 in.) on large forgings, is given in Table 14. The allowances listed are based on weight and shape, which are significant principally as an index of the amount of probable warpage. In all cases, the depths of cut given in Table 14 will also remove permissible amounts of decarburization. The tolerance and allowance for hot piercing of holes that are to be broached are given in Fig. 26.

Table 14 Machining allowance on each surface for typical steel forgings

Maximum weight of forging		Machining allowance per surface					
		Tail forgings		Flat forgings		Long forgings	
kg	lb	mm	in.	mm	in.	mm	in.
6.8	15	1.52-2.29	0.060-0.090	1.52-3.05	0.090-0.120	3.05	0.120

34	75	2.29-3.05	0.090-0.120	3.05	0.120	3.05	0.120
450	1000	3.05-4.83	0.120-0.190	3.05-6.35	0.120-0.250	4.83-6.35	0.190-0.250

Fig. 27 Computation of surface stock allowances for forgings that are to be machined

The precise effect of changes in section on the amount of distortion in heat treatment is unknown. For small parts, the usual method of overcoming distortion is by jig quenching or marquenching.

Decarburization. Because the loss of carbon greatly lowers the resistance to fatigue, the decarburized skin should be removed by machining in highly stressed areas. Table 15 lists the general limits for forgings of various sizes. The machining allowance is usually greater than the depths listed.

Table 15 Typical decarburization limits for steel forgings

Range of section size		Typical depth of decarburization	
mm	in.	mm	in.
<25	<1	0.8	0.031
25-100	1-4	1.2	0.047
100-200	4-8	1.6	0.062
>200	>8	3.2	0.125

Design for Tooling Economy. Considerable reduction in cost may result from forging designs that incorporate provisions for location of the forging for machining and inspection. Forgings that will be clamped to a faceplate or a machine-tool table should be provided with three bosses under the proposed clamping points to locate the part and to avoid both distortion and the tendency to rock (Fig. 28). When the quantity of parts is too small to justify tooling and holes are to be drilled or hot sheared in forging, the holes can be spotted with a cone angle steeper than the drill and about one-half to two-thirds of its diameter. This procedure enables accuracy of locations comparable with length tolerances and squareness predictable from thickness tolerances if the part is not specially located for machining.

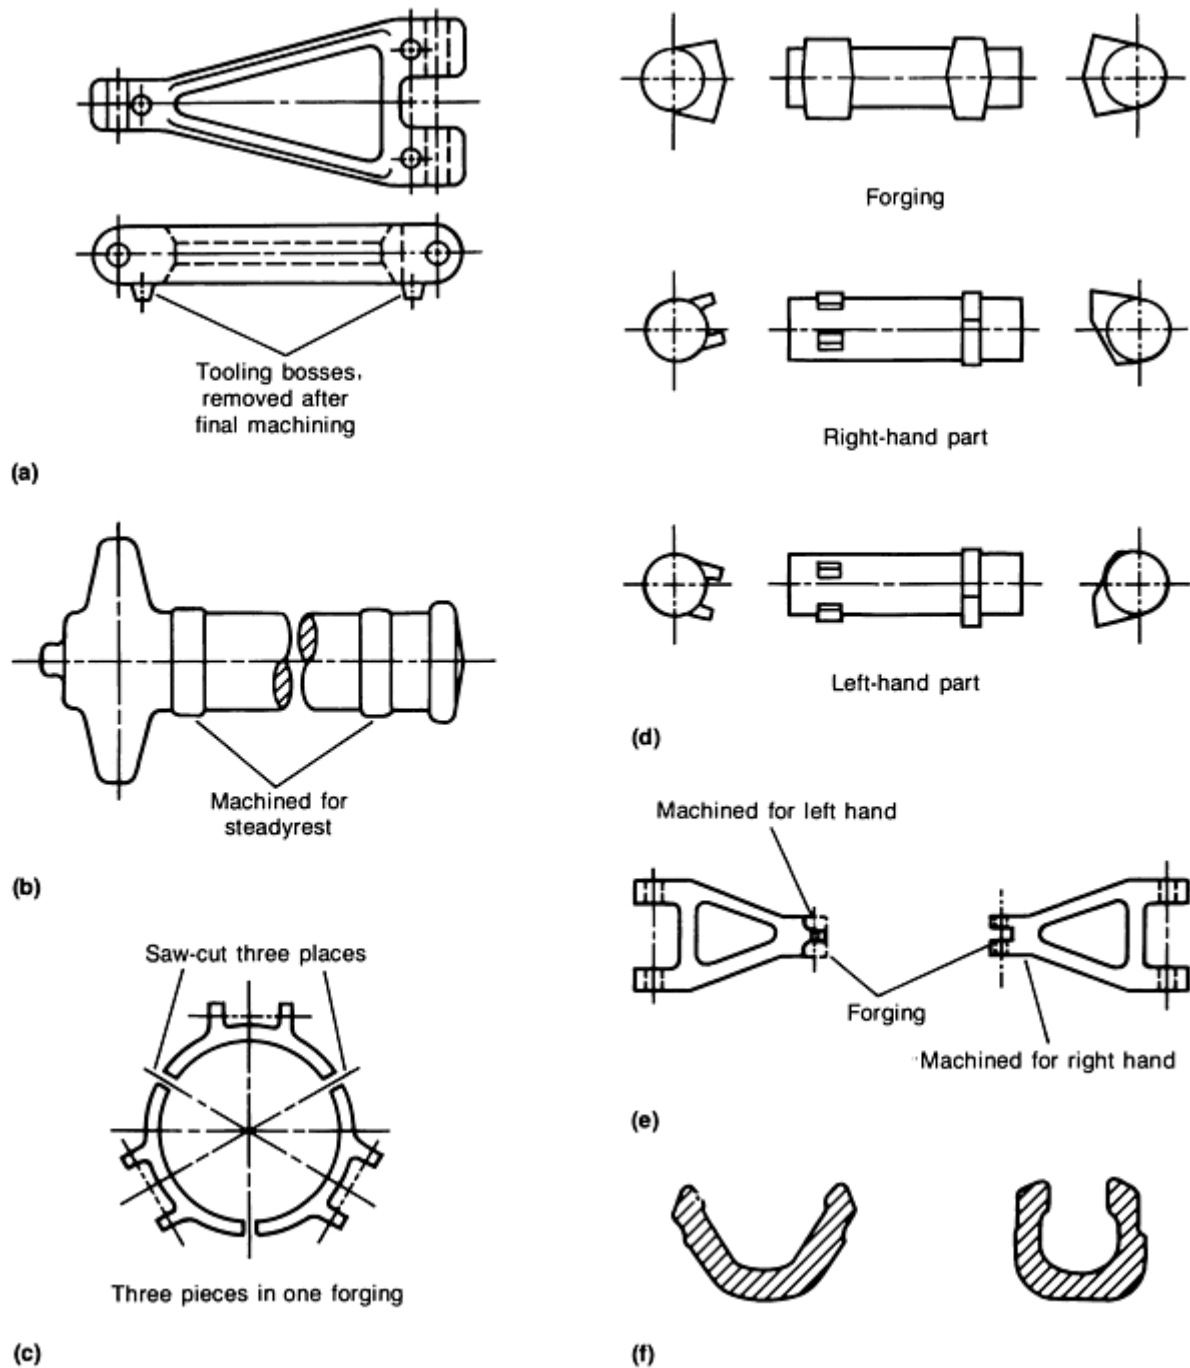

Fig. 28 Workpiece configurations that emphasize cost-effectiveness and versatility in terms of tooling design. (a), (b), and (c) Design for economy in tooling. (d) and (e) Combination of right-hand and left-hand parts in the same forging. (f) An unforgeable part that was bent to its final shape after preliminary forging

Long parts of irregular cross section that may have bow or camber should often be provided with steady-rest locations in the forging design for economical machining (Fig. 28). Machining economy and accuracy often result when a forging that

presents a problem in machining is designed as a Siamese forging with multiple parts on the same forgings to be saw-cut apart after machining is completed.

Special opportunities for economy are present in the design of right- and left-hand forgings to be transformed later (Fig. 28). The method shown for avoiding right- and left-hand forging tooling should always be used for the manufacture of small quantities, but may not be economical for large production. Figure 28 also shows a part that could not be forged without a secondary bending operation.

Design of Hot Upset Forgings

Hot heading, upset forging, or, more broadly, machine forging consists primarily of holding a bar of uniform cross section, usually round, between grooved dies and applying pressure on the end in the direction of the axis of the bar by using a heading tool so as to upset or enlarge the end into an impression of the die. The shapes generally produced include a variety of enlargements of the shank or multiple enlargements of the shank and reentrant angle configurations. Transmission cluster gears, pinion blanks, shell bodies, and many other shaped parts are adapted to production by the upset machine forging process. This process produces a looped grain flow of major importance for gear teeth. Simple, headed forgings can be completed in one step, while some that have large, configured heads or multiple upsets may require as many as six steps. Upset forgings weighing less than 0.45 to about 225 kg (1 to 500 lb) have been produced.

Machining Stock Allowances. The standard for machining stock allowance on any upset portion of the forging is 2.39 mm (0.094 in.), although allowances vary from 1.57 to 3.18 mm (0.062 to 0.125 in.), depending on the size of the upset, the material, and the shape of the part (Fig. 29a). Mismatch and shift of dies are each limited to 0.41 mm (0.016 in.) maximum. Mismatch is the location of the gripper dies with respect to each other, as shown in Fig. 29(a). Shift refers to the relation of the dies to the heading tool. Parting-line clearance is required in gripper dies for tangential clearance in order to avoid undercut and difficulty in the removal of the forging from the dies (Fig. 29a).

Fig. 29 Machining stock allowances for hot upset forgings. (a) Hot upset forging terminology and standards. (b) Probable shape of shear-cut ends. (c) Variation of corner radius with thickness of upset. These parts are the simplest forms of upset forgings. Dimensions given in inches

Tolerances for shear-cut ends have not been established. Figure 29(b) shows a shear-cut end on a 32 mm ($1\frac{1}{4}$ in.) diam shank. Straight ends can be produced by torch cutting, hacksawing, or abrasive wheel cutoff at a higher cost than shearing.

Corner radii should follow the contours of the finished part, with a minimum radius of 1.6 mm ($\frac{1}{16}$ in.). Radii are not required at the outside diameter of the upset face, but can be specified as desired. Variations in thickness of the upset require variations in radii, as shown in Fig. 29(c), because the origin of the force is farther removed and the die cavity is more difficult to fill. When a long upset is only slightly larger than the original bar size, a taper is advisable instead of a radius.

Fillets can conform to the finished contour in most cases. The absolute minimum should be 3.2 mm ($\frac{1}{8}$ in.) on simple upsets (Fig. 29c).

Tolerances for all upset-forged diameters are generally +1.6 mm, -0 mm ($+\frac{1}{16}$ in., -0 in.) except for thin sections of flanges and upsets relatively large in ratio to the stock sizes used, where they are +2.4 mm, -0 mm ($+\frac{3}{32}$ in., -0 in.). The increase in tolerances over the standard +1.66 mm, -0 mm ($+\frac{1}{16}$ in., -0 in.) is sometimes a necessity because of variations in size of hot-rolled mill bars, extreme die wear, or complexity of the part. Tolerances for unforged stem lengths are given in Table 16.

Table 16 Length tolerances for unforged stems of upset forgings

Maximum length		Minimum tolerance	
mm	in.	mm	in.
150	6	+1.59, -0.00	+0.062, -0.000
250	10	+2.39, -0.00	+0.094, -0.000
500	20	+3.18, -0.00	+0.125, -0.000
>500	>20	+3.96, -0.00	+0.156, -0.000

Draft angles may vary from 1 to 7°, depending on the characteristics of the forging design. Draft is needed to release the forging from the split dies; it also reduces the shearing of face surfaces in transfer from impression to impression. For an upset-forged part that requires several operations or passes, the dimensioning of lengths is determined on the basis of the design of each individual pass or operation.

Design of Specific Parts. A study of designs already being manufactured by the hot upset method of forging may serve as a guide for the development of similar applications. The following examples illustrate some typical exceptions to general design rules.

It can be seen from Fig. 30 that the size of stock required to produce the part determines the allowances required for finish machining, thickness of upset, diameter tolerances, and corner radii. The amount of upset stock required depends on bar size and determines whether the stock can be sheared, flame cut, or torch cut, or separated by another method. Figure 29(c) illustrates a few of the simplest upset parts.

Fig. 30 Design practice for upset forgings with specifications determined by raw material stock diameter. Tolerances (shown with + or - sign), allowances, and design rules for upset forgings of various typical or common shapes. Dimensions given in inches

Figure 31(a) shows a variation from the straight axle-shaft type of design in which the beveled head of the upset is confined in the heading tool. This method usually requires that the design recognize a position in the forging where a flash, or excess metal, must be trapped between the dies and heading tool. This is indicated in Fig. 31(a) by the 3.2 mm ($\frac{1}{8}$ in.) minimum dimension. Another problem encountered in designs of the type shown in Fig. 31(a) is the filling of the barrel section at the point of transition from original stock size to slightly increased diameter. As noted, an additional amount of finish is required, along with a generous radius.

Fig. 31 Design practice for upset forgings in which specifications depend on position of flash in workpiece. Tolerances (shown with + or - sign), allowances, and design rules for upset forgings. See text for discussion. Dimensions given in inches

The same problem, shown in Fig. 31(b), can be overcome by a taper blending from the bar size to the shoulder diameters. This type of design is expedient where the two diameters are within 9.5 mm ($\frac{3}{8}$ in.) of each other.

Figure 31(c) is basically an axle-shaft type of forging with a long pilot. Because the pilot part of the forging must be carried in the heading tools, draft is required for withdrawal from the tool and usually should be no less than $\frac{1}{2}^\circ$. The length of the pilot determines the amount of draft, which may range to a maximum taper of 3° . Another design rule to be recognized is that the pilot diameter in the heading tool should be 1.6 mm ($\frac{1}{16}$ in.) larger than the bar diameter to allow the stock to bottom in the heading tool. Contingent on the number of passes required in producing the forging, plus the mill tolerance for the particular bar size, the pilot end diameter may require a maximum of 3.2 mm ($\frac{1}{8}$ in.) over the bar diameter.

Figure 31(d) illustrates a typical transmission cluster gear forging. The drafts specified are a requirement for this type of forging because the part must be carried in the die after being partially produced. Of necessity, the neck diameter is determined by the stock size required to produce the part, plus an allowance to make a fit with the heading tool similar to Fig. 31(c).

Figure 31(e) shows the radius required when the pilot end must pass into the header. A small radius on the heading tool can scrape off metal along part of the length of the bar end and forge the loose chips into the face of the forged flange.

Figure 31(f) illustrates the minimum tapers and radii required for depressions in upset forgings. A larger draft angle or radius, or both, decreases the possibility of cold shuts.

Figures 31(g) and 31(j) show variations of size and design of forgings that are pierced or punched. In such forgings, the allowance for machining of the holes varies from 1.0 to 2.0 mm (0.040 to 0.080 in.), according to size, for parts that are to be broached.

In Fig. 31(g), the draft allowances required are similar to those of Fig. 31(d) to facilitate removal of the part from the die during and after forging. In Fig. 31(g), the large diameter shows a tolerance 0.8 mm ($\frac{1}{32}$ in.) larger than standard because the large flange fabricated in the first pass must be carried in the die while the front flange is being upset. Carrying the flange from pass to pass requires clearance of the flange in the die, and as the punch enters the forging, there is some upsetting action of the back flange, creating a slightly oval condition. The additional tolerance reflects not only die wear but also ovality. This also holds true for the neck diameter.

Figure 31(i) shows the amount of taper required when punching relatively deep holes. The length of the taper determines the amount of draft required to permit the punch to be withdrawn from the forging.

In addition to the various types of symmetrical forgings shown, some asymmetrical parts are readily forged. These include bolts of many sizes and designs, rod ends, trunnion forgings, steering sectors, universal joints, and a number of other parts with ends having various contours and dimensions.

Design of Hot Extrusion Forgings

Hot extrusion is used for making regular or irregular cup-shaped parts. The two principal types of hot extrusions are called straight extrusion, in which the metal is unconfined (Fig. 32a), and controlled extrusion, in which the metal is confined (Fig. 32b). More draft is allowed in a controlled extrusion because the flow of metal is restrained, and more stock is allowed because a flash is formed.

Fig. 32 Principal types of hot extrusion processes. (a) Straight extrusion. (b) Controlled extrusion

Size limitations for a range of small hot extrusions are given in Table 17. Tables 18 and 19 list the recommended dimensional tolerances applicable to straight extrusions and controlled extrusions, respectively.

Table 17 Recommended size limitations for hot extrusions made of carbon and alloy steel

Mismatch tolerances for 0.09 to 0.36 kg (0.2 to 0.8 lb) forgings are 0.20 mm (0.008 in.); 0.45 to 1.81 kg (1.0 to 4.0 lb), 0.25 to 0.30 mm (0.010 to 0.012 in.); 4.5 kg (10 lb), 0.41 mm (0.016 in.); 9.1 kg (20 lb), 0.56 mm (0.022 in.); and 14 kg (30 lb), 0.660 mm (0.026 in.). Mismatch is defined in Fig. 33. Mismatch tolerance must be added to other tolerances.

Fig. 33 Schematic showing mismatch in an extrusion. Definition of mismatch tolerance in terms of total indicator reading for values given in text

Machining allowance for forgings up to 6 m (20 ft) long, up to 305 mm (12 in.) OD, and 127 mm (5 in.) ID are 13 mm ($\frac{1}{2}$ in.) on length, 4.0 mm ($\frac{5}{32}$ in.) on the OD, and 3.2 mm ($\frac{1}{8}$ in.) on the ID.

Mechanical properties are dealt with in Table 20. A part of the extrusion was die forged and then extruded in the barrel section. In the area where the effect of the extrusion operation began at the end of the die-forged or hammered area,

the flow lines were very irregular and curved or bulged to the outside. The extrusion was approximately 203 mm (8 in.) in diameter, 1.2 m (4 ft) in length, and had a 19 mm ($\frac{3}{4}$ in.) wall thickness.

(a) Specimens with 50 mm (2 in.) gage length were standard 12.83 mm (0.505 in.) in diameter. Specimens with 25 mm (1 in.) gage length were subsize 6.35 mm (0.250 in.) in diameter.

(b) At bulge

Transverse specimens show a marked decrease in impact strength and ductility as measured by bend angle. In straight extrusion, there is no flash line; therefore, transverse flash-line tests could not be conducted.

Introduction

HIGH-STRENGTH LOW-ALLOY (HSLA) steels with excellent strength and toughness were originally developed as flat-rolled products for the Alaskan pipeline in the late 1960s.

Two HSLA families are acicular-ferrite steels (Ref 1) and pearlite-reduced steels (Ref 2). These steels contain microalloying additions of vanadium and niobium, and they have a yield strength of 480 MPa (70 ksi) and a Charpy V-notch fracture appearance transition temperature (FATT) of -60 °C (-75 °F). Typical thermomechanical processing of these materials involves reheating slabs to 1260 °C (2300 °F), with hot work continuing to 815 °C (1500 °F) and water spray cooling to 650 °C (1200 °F).

The objective of the researchers responsible for developing microalloy forging steels was to obtain the enhanced mechanical properties of hot-formed steel parts while simultaneously eliminating the need for heat treating of the steel. Elimination of the heat-treating operation reduces energy consumption and processing time as well as the material inventories resulting from intermediate processing steps.

Heat-treated forgings currently outperform alternative materials where strength, toughness, and reliability are primary considerations. However, methods must be found that achieve these benefits at lower cost. The goal of ferrous metallurgists, therefore, has been to achieve similar properties in steel forgings in the as-forged condition, that is, without subsequent heat treatment.

Unfortunately, the thermomechanical processing used for HSLA flat-rolled products cannot be readily transferred to hot forging. Typical hot forgings are produced from bars that are induction or gas heated to 1260 °C (2300 °F), then hot worked to 1120 °C (2050 °F). Grain growth and precipitate coarsening are rapid at these temperatures and are exacerbated by the mass effect of forgings compared with strip. Attempts to forge at temperatures low enough to optimize as-forged steel properties result in decreased equipment efficiency and excessive die wear.

Microalloying Elements

All microalloy steels contain small concentrations of one or more strong carbide-and nitride-forming elements. Vanadium, niobium, and titanium combine preferentially with carbon and/or nitrogen to form a fine dispersion of precipitated particles in the steel matrix. Table 1 summarizes the effects of the various elements.

Table 1 Effects of selected elements on the properties of microalloying steels

Element	Precipitation strengthening	Ferrite grain refinement	Nitrogen fixing	Structure modification
Vanadium	Strong	Weak	Strong	Moderate

Niobium	Moderate	Strong	Weak	None
Molybdenum	Weak	None	None	Strong
Titanium	None (<0.02% Ti) and strong (>0.05% Ti)	Strong	Strong	None

Vanadium. Precipitation strengthening is one of the primary contributors to microalloy steels; it is most readily achieved with vanadium additions in the 0.03 to 0.10% range. Vanadium also improves toughness by stabilizing dissolved nitrogen, which, in electric furnace melted steel, may be as high as 0.012%. There is a linear relationship between vanadium content and yield and tensile strength up to 0.15% V; it can exceed this level if sufficient nitrogen is present. The impact transition temperature also increases when vanadium is added (Fig. 1).

Fig. 1 Effect of vanadium on the tensile properties and FATT to a first-generation medium-carbon microalloy steel

Niobium can also have a strong precipitation-strengthening effect provided it is taken into solution at reheat and is kept in solution during forging. Its main contributions, however, are to form precipitates above the transformation temperature, and to retard the recrystallization of austenite, thus promoting a fine-grain microstructure having improved strength and toughness. Concentrations vary from 0.020 to 0.10% Nb.

Molybdenum is included in Table 1 because of its use in second-generation microalloy steels. It has the effect of greatly simplifying the process controls necessary in a forge shop for the application of these materials.

Titanium can behave as both a grain refiner and a precipitate strengthener, depending on its content (Ref 3). At compositions greater than 0.050%, titanium carbides begin to exert a strengthening effect. However, at this time, titanium is used commercially to retard austenite grain growth and thus improve toughness. Typically, titanium concentrations range from 0.010 to 0.020%.

Metallurgical Effects

The precipitation and dissolution characteristics of vanadium and niobium compounds in austenite differ significantly. Upon cooling from the forging temperature, niobium carbide begins to precipitate at about 1205 °C (2200 °F), as shown in Fig. 2. Without subsequent hot work, the precipitates continue to form and coarsen as the temperature falls to 925 °C (1700 °F). Continued hot working into the 900 °C (1650 °F) temperature range, however, retards austenite recrystallization and precipitation, resulting in the development of a refined austenite grain size.

Fig. 2 Precipitation and dissolution characteristics of vanadium and niobium carbides in austenite

Vanadium carbonitride precipitation begins at about 950 °C (1740 °F) and becomes complete during transformation. Because vanadium carbonitride is a relatively low-temperature product, precipitate coarsening during accelerated cooling from the forge is minimal, and the maximum precipitation-strengthening effect is achieved.

The toughness of all hot-worked microalloy steels improves when ferrite grain refinement is maximized by controlling the finish hot-working temperature. For example, the 20 J (15 ft · lbf) transition temperature for a niobium-containing low-carbon steel is reduced from 30 to -80 °C (85 to -110 °F) by reducing the finishing temperature from 1050 to 900 °C (1920 to 1650 °F). The improvement is independent of the reheat temperature.

The solubility of niobium carbide in austenite is mainly a function of temperature and carbon content. The solid solubility limit of niobium in austenite can be readily exceeded at normal forging temperature. The same is true of titanium nitride precipitates. The opportunity therefore exists to avoid abnormal grain growth at forging temperatures by using a suitable concentration of either titanium or niobium.

The toughness of the acicular-ferrite steels originally designed for use on the Alaskan pipeline was a result of their complex microstructures, which were brought about by the addition of molybdenum to a 0.06% C (max), 1.8% Mn steel. Pearlite transformation is suppressed in these steels, and a ferrite microstructure is obtained over a wide range of cooling rates. This same microstructure can be achieved in small forgings. Figure 3 shows typical thermal cycles for conventional quench and temper and for microalloy process routes.

Fig. 3 Thermal cycles for conventional (a) and microalloy (b) steels. Source: Ref 4

The metallurgical fundamentals described above were first applied to forgings in the early 1970s. A West German composition, 49MnVS3 (nominal composition: 0.47C-0.20Si-0.75Mn-0.060S-0.10V), was successfully used for automotive connecting rods. The steel was typical of the first generation of microalloy steels, with a medium carbon content (0.35 to 0.50% C) and additional strengthening through vanadium carbonitride precipitation. The parts were subjected to accelerated air cooling directly from the forging temperature. The AISI grade 1541 microalloy steel with either niobium or vanadium has been used in the United States for similar automotive parts for many years.

First-generation microalloy forging steels generally have ferrite-pearlite microstructures, tensile strengths above 760 MPa (110 ksi), and yield strengths in excess of 540 MPa (78 ksi). The room-temperature Charpy V-notch toughness of first-generation forgings is typically 7 to 14 J (5 to 10 ft · lbf), ambient. It became apparent that toughness would have to be significantly improved to realize the full potential of microalloy steel forgings.

Second-generation microalloy steels were introduced in about 1986 (Ref 5). These are typified by the West German grade 26MnSiVS7 (nominal composition: 0.26C-0.70Si-1.50Mn-0.040S-0.10V-0.02Ti). The carbon content of these steels was reduced to between 0.10 and 0.30%. They are produced with either a ferrite-pearlite microstructure or an acicular-ferrite structure. The latter results from the suppression of pearlite transformation products by an addition of

about 0.10% Mo. Titanium additions have also been made to these steels to improve impact toughness even further. Two typical second-generation microalloy steel compositions used in the United States are listed in Table 2.

Table 2 Typical second-generation microalloy steel compositions used in the United States

Grade	Composition, %							
	C	Mn	P	S	Si	Mo	V	N
1524MoV	0.22	1.54	0.014	0.036	0.35	0.11	0.11	0.011

One of the primary concerns of any steel user is the consistency of finished-part properties. Heat treatment has successfully addressed this concern, and a method must be found to ensure the consistency of finished-part properties for microalloy steels. One disadvantage of ferrite-pearlite microalloy steels is that the finished strength and hardness are functions of the cooling rate. Cooling rate can vary because of either process changes or part geometry.

Figure 4 shows the effect of cooling rate on the yield strength of a forging made from three grades of steel (Ref 6). The 1030 grade has been microalloyed with 0.03% Nb, the other two grades have compositions as shown in Table 2. Forging temperature was 1260 °C (2300 °F); the cooling conditions examined were traditional bin cooling after trimming the hot forging, still-air cooling of forgings isolated from each other, and forced-air cooling on a conveyor followed by final tub cooling from 595 °C (1100 °F). The 1524V grade performs as predicted for ferrite-pearlite steels: Strength increases with cooling rate. The 1524MoV steel is neither as sensitive to cooling rate nor does it develop the same strength as the ferrite-pearlite steel.

Fig. 4 Effect of cooling rate on the yield strength of three grades of forgings: 1030, 1524V, and 1524MoV

Ambient-temperature Charpy V-notch impact tests on forgings in the same three cooling conditions show that the 1524MoV steel has a consistent 20 J (15 ft · lbf) of energy absorbed independent of the cooling rate. The 1524V grade must be conveyor cooled to achieve this toughness (Fig. 5). The molybdenum-treated steel removes the variable of accelerated cooling from the process, an advantage to the hot forger and end user because conveyors are unnecessary. It also makes possible the use of microalloy steels in forgings with cross sections up to at least 75 mm (3 in.) thick. It should be noted that a reduction in forging temperature would result in improved toughness in these steels. Figure 6 shows the continuous cooling transformation diagram for the 1524MoV steel.

Fig. 5 Effect of cooling rate on Charpy V-notch impact toughness of two second-generation microalloy steels. Cooling rates ranged from 1.3 °C/s (2.4 °F/s) (bin cooling) to 2.7 °C/s (4.8 °F/s) (forced-air cooling). The molybdenum-containing steel is unaffected by cooling conditions.

Fig. 6 Continuous cooling transformation diagram for 1524MoV steel. The circled numbers correspond to the HV

hardness of microstructures produced by cooling at the rates shown. Source: Ref 7

Titanium-treated microalloy steels are currently in production in the United States, Germany, and Japan. The resistance to grain coarsening imparted by titanium nitride precipitation increases the toughness of the forgings. The ultimate strength of first- and second-generation microalloy steels is adequate for many engineering applications, but these steels do not achieve the toughness of conventional quenched and tempered alloys under normal hot-forging conditions.

Third-generation microalloy steels went into commercial production in the United States in 1989. These steels differ from their predecessors in that they are direct quenched from the forging temperature to produce microstructures of lath martensite with uniformly distributed temper carbides (Fig. 7). Without subsequent heat treatment, these materials achieve properties, including toughness, similar to those of standard quenched and tempered steels (Fig. 8 and 9). The metallurgical principles behind this development are as follows:

- Niobium additions sufficient to exceed the solubility limit at the forging temperature. Undissolved Nb(CN) retards the recrystallization and grain growth of austenite during forging, trimming, and entry into the quenchant
- Composition control to ensure that the martensite finish temperature is above 205 °C (400 °F)
- A fast cold-water quench is performed on a moving conveyor through a spray chamber or by other appropriate equipment
- The relatively high martensite finish temperature, combined with the mass effect of a forging, results in an auto-tempered microstructure with excellent toughness and a hardness of 38 to 43 HRC. Section thicknesses of up to 50 mm (2 in.) have been successfully produced

Fig. 7 Microstructure of a third-generation microalloy forging steel, which consists of lath martensite and uniformly distributed auto-tempered carbides

Fig. 8 Bar graph showing that direct-quenched third-generation steels absorb much more energy in Charpy V-notch impact testing at -30 °C (-20 °F) than earlier microalloy grades. The 20 J (15 ft · lbf) energy absorbed criterion used to qualify older alloys no longer applies.

Fig. 9 Impact transition temperature profile of a third-generation microalloy steel in Charpy V-notch testing. New alloys maintain adequate toughness to -60 °C (-76 °F) and below.

The newest generation of microalloy forging steels (1989) has five to six times the toughness at -30 °C (-20 °F) and twice the yield strength of second-generation materials. No special forging practices are required except for the use of a water-cooling system. In a comparison of a third-generation microalloy steel to two standard quenched and tempered carbon and alloy steels (1040 and 4140), properties of the direct quenched microalloy grade were very similar to those of quenched and tempered 4140. The hardness of all three materials tested was 40 HRC (Fig. 10). Additional information on the effect of various elements on the metallurgy of steels is available in the article "Bulk Formability of Steels" in this Volume.

Fig. 10 Comparison of impact transition properties for third-generation microalloy steel to standard quenched

and tempered carbon (1040) and alloy (4140) steel grades. All materials tested at 40 HRC hardness.

Future Outlook

Recent advances in titanium-treated and direct-quenched microalloy steels provide new opportunities for the hot forger to produce tough, high-strength parts without special forging practices. Product evaluations of these microalloy steels indicate that they are comparable to conventional quenched and tempered steels.

Warm forging continues to make steady progress as a cost-effective, precision manufacturing technique because it significantly reduces machining costs. Microalloy steels austenitized at 1040 °C (1900 °F), cooled to a warm forging temperature of 925 °C (1700 °F), forged, and cooled by air or water (depending on composition), will produce a range of physical properties. The resulting cost savings has the potential to improve the competitive edge that forging has over other manufacturing techniques.

Steel Castings

Revised by Malcolm Blair, Steel Founders' Society of America

Introduction

STEEL CASTINGS are produced by pouring molten steel of the desired composition into a mold of the desired configuration and allowing the steel to solidify. The mold material may be silica, zircon, chromite sand, olivine sand, graphite, metal, or ceramic. The choice of mold material depends on the size, intricacy, dimensional accuracy of the casting, and cost. While the producible size, surface finish, and dimensional accuracy of castings vary widely with the type of mold, the properties of the cast steel are not affected significantly.

Steel castings can be made from any of the many types of carbon and alloy steel produced in wrought form. Those castings produced in any of the various types of molds and wrought steel of equivalent chemical composition respond similarly to heat treatment, have the same weldability, and have similar physical and mechanical properties. However, cast steels do not exhibit the effects of directionality on mechanical properties that are typical of wrought steels. This nondirectional characteristic of cast steel mechanical properties may be advantageous when service conditions involve multidirectional loading.

Another difference between steel castings and wrought steel is the deoxidation required during steelmaking. Cast steels are made only from fully killed (deoxidized) steel in a foundry, while wrought products can be made from rimmed, semikilled, or killed steel ingots in a mill. The method of producing the killed steel used for a casting may also differ from that used for a wrought product because of differences in the tapping temperatures required in casting and ingot production.

However, the salient features of producing killed steel in a casting foundry are the same as those features important to the production of fully killed steel ingots. For the deoxidation of carbon and low-alloy steels (that is, for control of their oxygen content), aluminum, titanium, and zirconium are used. Of these, aluminum is used more frequently because of its effectiveness and low cost. Unless otherwise specified, the normal sulfur limit for carbon and low-alloy steels is 0.06%, and the normal phosphorus limit is 0.05%.

Classifications and Specifications

The steel castings discussed in this article are divided into four general groups according to composition:

- Low-carbon steel castings
- Medium-carbon steel castings
- High-carbon steel castings
- Low-alloy steel castings

Other types of steel castings are discussed in separate articles on heat-resistant castings, stainless (corrosion-resistant) steel castings, and austenitic manganese steels in this Volume.

Carbon steels contain only carbon as the principal alloying element. Other elements are present in small quantities, including those added for deoxidation. Silicon and manganese in cast carbon steels typically range from 0.25 to about 0.80% Si and 0.50 to about 1.00% Mn.

Like wrought steels, carbon cast steels can be classified according to their carbon content into three broad groups:

- *Low-carbon steels:* 0.20% C or less
- *Medium-carbon steels:* 0.20 to 0.50% C
- *High-carbon steels:* 0.50% C or more

Carbon content is a principal factor affecting the mechanical properties of these steels. The other important factor is the method of heat treatment.

Figure 1 shows the basic trends of the mechanical properties of cast carbon steels as a function of carbon content for four different heat treatments. For a given heat treatment, a higher carbon content generally results in higher hardness and strength levels with lower ductility and toughness values. Further information on the properties of carbon cast steels is contained in subsequent sections of this article.

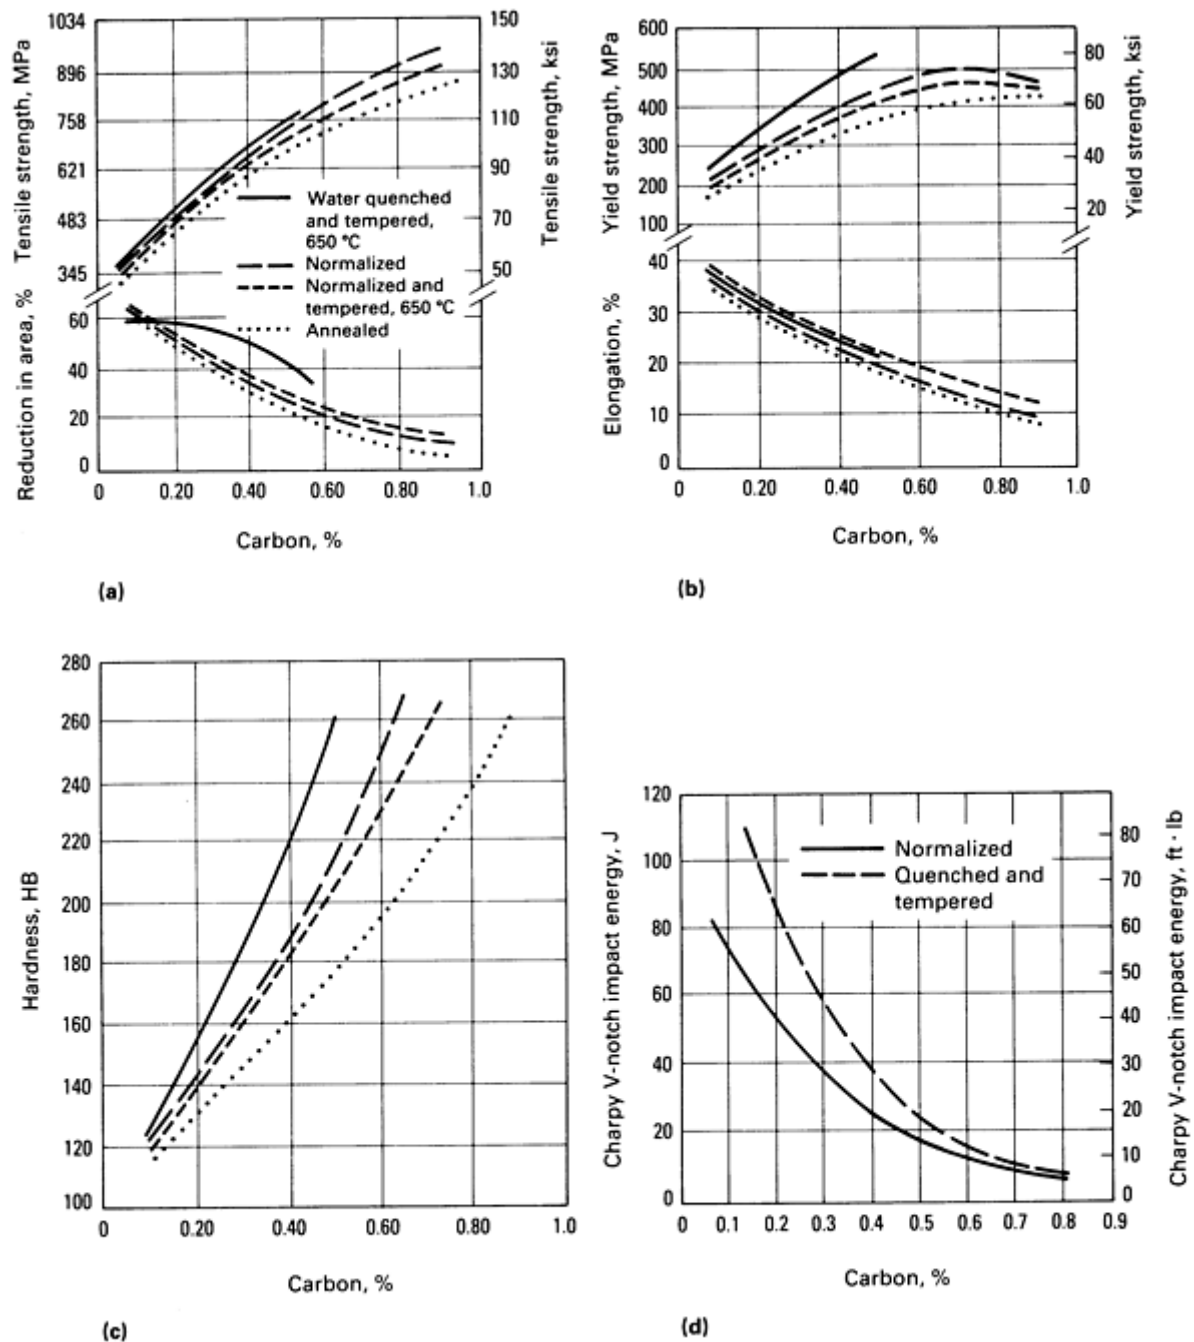

Fig. 1 Properties of cast carbon steels as a function of carbon content and heat treatment. (a) Tensile strength and reduction of area. (b) Yield strength and elongation. (c) Brinell hardness. (d) Charpy V-notch impact energy

Low-alloy steels contain, in addition to carbon, alloying elements up to a total alloy content of 8%. Cast steels containing more than the following amounts of a single alloying element are considered low-alloy cast steel:

Element	Amount, %
---------	-----------

Manganese	1.00
Silicon	0.80
Nickel	0.50
Copper	0.50
Chromium	0.25
Molybdenum	0.10
Vanadium	0.05
Tungsten	0.05

Aluminum, titanium, and zirconium are used for the deoxidation of low-alloy steels. Of these elements, aluminum is used most frequently because of its effectiveness and low cost.

Numerous types of cast low-alloy steel grades exist to meet the specific requirements of the end-use, such as structural strength and resistance to wear, heat, and corrosion. The designations of the American Iron and Steel Institute (AISI) and the Society of Automotive Engineers (SAE) have historically been used to identify the various types of steel by their principal alloy content. Cast steels, however, do not precisely follow the compositional ranges specified by AISI and SAE designations for wrought steels. In most cases, the cast steel grades contain 0.30 to 0.65% Si and 0.50 to 1.00% Mn, unless otherwise specified. The principal low-alloy cast steel designations, their AISI and SAE equivalents, and their alloy type are:

Cast steel designation	Nearest wrought equivalent	Alloying elements
1300	1300	Manganese
8000, 8400	8000, 8400	Manganese, molybdenum
80B00	80B00	Manganese, molybdenum, boron
2300	2300	Nickel
8600, 4300	8600, 4300	Nickel, chromium, molybdenum

9500	9500	Manganese, nickel, chromium, molybdenum
4100	4100	Chromium, molybdenum

The 8000, 8400, 2300, and 9500 alloy types are used extensively as cast steels. There are additional alloy types that are infrequently specified as cast steels, that is, 3100 (nickel-chromium), 3300 (nickel-chromium), 4000 (molybdenum), 5100 (chromium), 6100 (chromium-vanadium), 4600 (nickel-molybdenum), and 9200 (silicon). Further information on the elements used in alloy steel castings is provided in the section "Low-Alloy Cast Steels" of this article.

Specifications. Steel castings are usually purchased to meet specified mechanical properties, with some restrictions on chemical composition. Tables 1 and 2 list the requirements given in various specifications of the American Society of Testing and Materials (ASTM) and in SAE J435c. Table 1 primarily lists carbon steel castings (with some comparable low-alloy types), while Table 2 lists several low-alloy cast steels and some cast steels with chromium contents up to 10.0%.

Table 1 Summary of specification requirements for various carbon steel castings

Unless otherwise noted, all the grades listed in this table are restricted to a phosphorus content of 0.40% max and a sulfur content of 0.045% max.

(a) Where a single value is shown, it is a minimum.

(b) Where a single value is shown, it is a maximum.

(c) For each reduction of 0.01% C below the maximum specified, an increase of 0.04% Mn above the maximum specified is permitted up to the maximums given in the applicable ASTM specifications.

(d) Grades may also include low-alloy steels; see Table 2 for the stronger grades of ASTM A 148.

(e) Unless specified by purchaser, the compositions of cast steels in ASTM A 148 are selected by the producer in order to achieve the specified mechanical properties.

(f) Purchased on the basis of hardenability, with manganese and other elements added as required.

(g) Specified residual elements include 0.30% Cu max, 0.50% Ni max, 0.50% Cr max, 0.20% Mo max, and 0.03% V max, with the total residual elements not exceeding 1.00%.

- (h) These ASTM specifications also include alloy steel castings for the general type of applications listed in the Table.
- (i) Testing temperature of -32 °C (-25 °F).
- (j) Charpy V-notch impact testing at the specified test temperature with an energy value of 18 J (13 ft · lbf) min for two specimens and an average of three.
- (k) Testing temperature of -46 °C (-50 °F).
- (l) Specified residual elements of 0.03% V, 0.50% Cu, 0.50% Ni, 0.40% Cr, and 0.25% Mo, with total amount not exceeding 1.00%. Sulfur and phosphorus content, each 0.025% max

- (b) When a single value is shown, it is a minimum.
- (c) When a single value is shown, it is a maximum.
- (d) Unless specified by the purchaser, the compositions of cast steels in ASTM A 148 are selected by the producer and therefore may include either carbon or alloy steels; see Table 1 for the lower-grade steels specified in ASTM A 148.
- (e) 0.06% S (max), 0.05% P (max).
- (f) 0.020% S (max), 0.020% P (max).
- (g) Similar to the cast steel in ASTM A 148.
- (h) 0.045% S (max), 0.040% P (max).
- (i) When residual maximums are specified for copper, nickel, nickel, chromium, tungsten, and vanadium, their total content shall not exceed 1.00%.
- (j) 0.050% Cu (max), 0.10% W (max), 0.045% S(max), 0.04% P (max).
- (k) When residual maximums are specified for copper, nickel, chromium, tungsten, and vanadium, their total residual content shall not exceed 0.60%.
- (l) 0.35% Cu (max), 0.03% V (max), 0.015% S (max), 0.020% P (max).
- (m) 0.15-0.25% V.
- (n) The specified residuals of copper, nickel, chromium, and molybdenum (plus tungsten), shall not exceed a total content of 1.00%.
- (o) Includes the residual content of tungsten.
- (p) 0.50% Cu (max), 0.10% W (max), 0.03% V (max), 0.045% S (max), 0.04% P (max).
- (q) Material class 7A is a proprietary steel and has a maximum thickness of 63.5 mm ($2\frac{1}{2}$ in.).
- (r) Specified elements include 0.15-0.50% Cu, 0.03-0.10% V, and 0.002-0.006% B.
- (s) When residual maximums are specified for copper, nickel, chromium, tungsten, molybdenum, and vanadium, their total content shall not exceed 0.50%.

- (t) When residual maximums are specified for copper, nickel, chromium, tungsten, and vanadium, their total content shall not exceed 0.75%.
- (u) Low-carbon grade with double austenitization.
- (v) For each reduction of 0.01% C below the maximum, an increase of 0.04% Mn is permitted up to a maximum of 2.30%.
- (w) 0.20% Cu (max), 0.10% W (max), 0.02% V (max), 0.02% S (max), 0.02% P (max)

In the low-strength ranges, some specifications limit carbon and manganese content, usually to ensure satisfactory weldability. In SAE J435c, carbon and manganese are specified to ensure that the minimum desired hardness and strength are obtained after heat treatment. For special applications, other elements may be specified either as maximum or minimum, depending on the characteristics desired.

The ASTM specifications that include carbon and low-alloy grades of steel castings are A 216, A 217, A 352, A 356, A 389, A 487, and A 757. The ASTM specifications with grades of carbon steel castings are listed in Table 1. Table 2 lists the requirements for the low-alloy classes of steel castings given in some of the ASTM specifications mentioned above. In addition, ASTM specifications may address common requirements of all steel castings for a particular type of application. For example, ASTM A 703 specifies the general requirements of steel castings for pressure-containing parts.

If only mechanical properties are specified, the chemical composition of castings for general engineering applications is usually left to the discretion of the casting supplier. For specific applications, however, certain chemical composition limits have been established to ensure the development of specified mechanical properties after proper heat treatment, as well as to facilitate welding, uniform response to heat treatment, or other requirements. Hardness is specified for most grades of SAE J435c to ensure machinability, ease of inspection for high production rate items, or certain characteristics pertaining to wear.

SAE J435c includes three grades, HA, HB, and HC, with specified hardenability requirements. Figure 2 plots hardenability requirements, both minimum and maximum, for these steels. Hardenability is determined by the end-quench hardenability test described in the article "Hardenability of Carbon and Low-Alloy Steels" in this Volume. Other specifications require minimum hardness at one or two locations on the end-quench specimen. In general, hardenability is specified to ensure a predetermined degree of transformation from austenite to martensite during quenching, in the thickness required. This is important in critical parts requiring toughness and optimum resistance to fatigue.

Fig. 2 End-quench hardenability limits for the hardenability grades of cast steel specified in SAE J435c. The nominal carbon content of these steels is 0.30% C (see Table 1). Manganese and other alloying elements are added as required to produce castings that meet these limits.

Among the most commonly selected grades of steel castings are, first, a medium-carbon steel corresponding to ASTM A 27 65-35 or SAE 0030 and second, a higher-strength steel, often alloyed and fully heat treated, similar to ASTM A 148 105-85 or SAE 0105.

Particularly when the purchaser heat treats a part after other processing, a casting will be ordered to compositional limits closely equivalent to the AISI-SAE wrought steel compositions, with somewhat higher silicon permitted. As in other steel

castings, it is best not to specify a range of silicon, but to permit the foundry to utilize the silicon and manganese combination needed to achieve required soundness in the shape being cast. The silicon content is frequently higher in cast steels than for the same nominal composition in wrought steel. Silicon above 0.80% is considered an alloy addition because it contributes significantly to resistance to tempering.

Railroad equipment manufacturers and other major users of steel castings may prefer their own or industry association specifications. Users of steel castings for extremely critical applications, such as aircraft, may use their own, industry association, or special-purpose military specifications. Foundries frequently make nonstandard grades for special applications or have their own specification system to meet the needs of the purchaser. Savings may be realized by using a grade that is standard with a foundry, especially for small quantities.

Low-Carbon Cast Steels

Low-carbon cast steels are those with a carbon content of less than 0.20%. Most of the tonnage produced in the low-carbon classification contains between 0.16 and 0.19% C, with 0.50 to 0.80% Mn, 0.05% P (max), 0.06% S (max), and 0.35 to 0.70% Si. In order to obtain high magnetic properties in electrical equipment, the manganese content is usually held between 0.10 and 0.20%. The properties of these dynamo steels may be slightly below those of typical low-carbon cast steels because of their manganese content.

Figure 1 includes the mechanical properties of carbon cast steels with low-carbon contents within the range of about 0.10 to 0.20%. There is very little difference between the properties of the low-carbon steels resulting from the use of normalizing heat treatments, and the properties of those that are fully annealed. In cast steels, as in rolled steels of this composition, increasing the carbon content increases strength and decreases ductility. Although the mechanical properties of low-carbon cast steels are nearly the same in the as-cast condition as they are after annealing, low-carbon steel castings are often annealed or normalized to relieve stresses and refine the structure.

Low-carbon steel castings are made in two important classes. One may be termed railroad castings, and the other miscellaneous jobbing castings. The railroad castings consist mainly of comparatively symmetrical and well-designed castings for which adverse stress conditions have been carefully studied and avoided.

Miscellaneous jobbing castings present a wide variation in design and frequently involve the joining of light and heavy sections. Varying sections make it more difficult to avoid high residual stress in the as-cast shape. Because residual stresses of large magnitude cannot be tolerated in many service applications, stress relieving becomes necessary. Therefore, the annealing of those castings is decidedly beneficial even though it may cause little improvement of mechanical properties. Castings for electrical or magnetic equipment are usually fully annealed because this improves the electrical and magnetic properties.

An increase in mechanical properties can be obtained by quenching and tempering, provided the design of the casting is such that it can be liquid quenched without cracking. Impact resistance is improved by quenching and tempering, especially if a high tempering temperature is employed.

Uses. As has been mentioned, important castings for the railroads are produced from low-carbon cast steels. Some castings for the automotive industry are produced from this class of steel, as are annealing boxes, annealing bottoms, and hot-metal ladles. Low-carbon steel castings are also produced for case carburizing, by which process the castings are given a hard, wear-resistant exterior while retaining a tough, ductile core. The magnetic properties of this class of steel make it useful in the manufacture of electrical equipment. Free-machining cast steels containing 0.08 to 0.30% sulfur are also produced in low-carbon grades.

Medium-Carbon Cast Steels

The medium-carbon grades of cast steel contain 0.20 to 0.50% C and represent the bulk of steel casting production. In addition to carbon, they contain 0.50 to 1.50% Mn, 0.05% P (max), 0.06% S (max), and 0.35 to 0.80% Si. The mechanical properties at room temperature of cast steels containing from 0.20 to 0.50% C are included in Fig. 1. Steels in this carbon range are always heat treated, which relieves casting strains, refines the as-cast structure, and improves the ductility of the steel.

Unlike low-carbon castings, when medium-carbon steel castings are fully annealed, it is possible to increase the yield strength, the reduction of area, and the elongation over the entire range, compared to as-cast properties (Fig. 14). This

increase is pronounced for steel with a carbon content between 0.25 and 0.50%. The hardness and tensile strength can be expected to fall off slightly following full annealing.

Fig. 14 Effect of annealing on the mechanical properties of medium-carbon steel castings

A very large proportion of steel castings of this grade are given a normalizing treatment, following by a tempering treatment. The improvement in mechanical properties of medium-carbon cast steel that may be expected after normalizing or normalizing and tempering is shown in Fig. 1.

If the design of a casting is suitable for liquid quenching, further improvements are possible in the mechanical properties. In fact, to develop mechanical properties to the fullest degree, steel castings should be heat treated by liquid quenching and tempering. Commercial procedure calls for tempering to obtain the desired strength level. Tempering temperatures of 650 to 705 °C (1200 to 1300 °F) are usually used to obtain higher ductility and impact properties.

High-Carbon Cast Steels

Cast steels containing more than 0.50% C are classified as high-carbon steels. This grade also contains 0.50 to 1.50% Mn, 0.05% P (max), 0.05% S (max), and 0.35 to 0.70% Si. The mechanical properties of high-carbon steels at room temperature are shown in Fig. 1. High-carbon cast steels are often fully annealed. Occasionally, a normalizing and tempering treatment is given, and for certain applications an oil quenching and tempering treatment may be used.

The microstructure of high-carbon steel is controlled by the heat treatment. Carbon also has a marked influence, for example, giving 100% pearlitic structure at eutectoid composition (~0.83% carbon). Higher proportions of carbon than eutectoid composition will increase the proeutectoid cementite, which is detrimental to the casting if it forms a network at the grain boundaries because of improper heat treatment (for example, slow cooling from above the A_{cm} temperature). Faster cooling will prevent the formation of this network and, hence, improve the properties.

Low-Alloy Cast Steels

Low-alloy cast steels contain a total alloy content of less than 8%. These steels have been developed and used extensively for meeting special requirements that cannot be met by ordinary plain carbon steels with low hardenability. The addition of alloys to plain carbon steel castings may be made for any of several reasons, such as to provide higher hardenability, increased wear resistance, higher impact resistance at increased strength, good machinability even at higher hardness, higher strength at elevated and low temperatures, and better resistance to corrosion and oxidation than the plain carbon steel castings. These materials are produced to meet tensile strength requirements of 485 to 1380 MPa (70 to 200 ksi), together with some of the above special requirements.

Alloy cast steels are used in machine tools; high-speed transportation units; steam turbines; valves and fittings; railway, automotive, excavating, and chemical processing equipment; pulp and paper machinery; refinery equipment; rayon machinery; and various types of marine equipment. They are also used in the aeronautics field.

Low-alloy cast steels may be divided into two classes according to use: those used for structural parts of increased strength, hardenability, and toughness, and those resistant to wear, abrasion, or corrosive attack under low- or high-temperature service conditions. There can be no sharp distinction between the two classes because many steels serve in both fields.

The present trend toward decreasing weight through the use of high-strength materials in lighter sections has had a marked effect on the development of low-alloy cast steels. Low-alloys grades, such as those in the 86xx, 41xx, and 43xx families, are capable of producing mechanical properties with a yield strength 50% higher and a tensile strength 40% higher than carbon steels, with a ductility and impact resistance at least equal to unalloyed steels. Some 75 to 100 combinations of the available alloying materials have been regularly or occasionally used. It is doubtful that this many variations in composition are necessary or economical.

Alloying Elements. The compositions of low-alloy cast steels are primarily characterized by carbon contents under 0.45% and by small amounts of alloying elements, which are added to produce certain specific properties. Low-alloy steels are applied when strength requirements are higher than those obtainable with carbon steels. Low-alloy steels also have better toughness and hardenability than do carbon steels.

Carbon-Manganese Cast Steels. Manganese is the cheapest of the alloying elements and has an important effect in increasing the hardenability of steel. For this reason, many of the low-alloy cast steels now contain between 1 and 2% manganese. In the normalized steels in which grain refinement is also needed, vanadium, titanium, or aluminum is often added.

Carbon-manganese steels containing 1.00 to 1.75% Mn and 0.20 to 0.50% C have received considerable attention from engineers in the past because of the excellent properties that can be developed with a single, relatively inexpensive alloying element and by a single normalizing or normalizing and tempering heat treatment. Carbon-manganese steels are also referred to as medium-manganese steels and are represented by the cast 1300 series of steels (1.60 to 1.90% Mn).

Manganese-molybdenum cast steels are very similar to the medium-manganese steels with the added characteristics of high yield strength at elevated temperatures, higher ratio of yield strength to tensile strength at room temperature, greater freedom from temper embrittlement, and greater hardenability. Therefore, these steels have replaced medium-manganese steel for certain applications.

There are two general grades of manganese-molybdenum cast steels:

- 8000 series (1.0 to 1.35% Mn, 0.10 to 0.30% Mo)
- 8400 series (1.35 to 1.75% Mn, 0.25 to 0.55% Mo)

For both of these alloy types, the selected carbon content is frequently between 0.20 and 0.35%, depending on the heat treatment employed and the strength characteristics desired.

Manganese-Nickel-Chromium-Molybdenum Cast Steels. The cast 9500 series low-alloy steels are primarily produced for their high hardenability. Sections exceeding 125 mm (5 in.) in thickness can be quenched and tempered to obtain a fully tempered martensitic structure. The composition range employed for the 9500 series is:

Nickel or molybdenum with manganese refines the grain structure to a lesser extent than does vanadium, titanium, or aluminum, but each is important for increasing the ability of the steel to air harden. Chromium and vanadium impart considerable hardenability. Vanadium-containing steels are sometimes precipitation hardening and, therefore, may have higher tensile and yield strengths.

Element	Composition, %
Manganese	1.30-1.60
Nickel	0.40-0.70
Chromium	0.55-0.75
Molybdenum	0.30-0.40

Nickel Cast Steels. Among the oldest alloy cast steels are those containing nickel. Nickel and nickel-vanadium steels are used for parts exposed to subzero conditions (such as return headers, valves, and pump castings in oil-refinery dewaxing processes) because of good notch toughness at lower temperatures. These steels are characterized by high tensile strength and elastic limit, good ductility, and excellent resistance to impact. The cast steels of the 2300 series contain 2.0 to 4.0% Ni, depending on the grade required.

Nickel-vanadium and nickel-manganese cast steels are used for structural purposes requiring wear resistance and high strength. The manganese-molybdenum cast steels are also used in these applications.

Nickel-Chromium-Molybdenum Cast Steels. The addition of molybdenum to nickel-chromium steel significantly improves hardenability and makes the steel relatively immune to temper embrittlement. Nickel-chromium-molybdenum cast steel is particularly well suited to the production of large castings because of its deep-hardening properties. In addition, the ability of these steels to retain strength at elevated temperatures extends their usefulness in many industrial applications.

Chromium-Molybdenum Cast Steels. Chromium contents of about 1.00% or more provide a nominal improvement in elevated-temperature properties. Cast steels containing chromium, molybdenum, vanadium and tungsten have given good service in valves, fittings, turbines, and oil refinery parts, all of which are subjected to steam temperatures up to 650 °C (1200 °F).

The chromium cast steels (5100 series, 0.70 to 1.10% Cr) are not in common use in the steel casting industry. Although chromium leads the field as an alloying element for wear-resistant steels, it is seldom used alone. For example, the chromium-molybdenum steels are widely used.

Copper-Bearing Cast Steels. There are several types of copper-containing steels. Selection among these various types is primarily based on either their atmospheric-corrosion resistance (weathering steels) or the age-hardening characteristics that copper adds to steel.

High-strength cast steels cover the tensile strength range of 1200 to 2070 MPa (175 to 300 ksi). Cast steels with these strength levels and with considerable toughness and weldability were originally developed for ordnance applications. These cast steels can be produced from any of the above medium-alloy compositions by heat treating with liquid-quenching techniques and low tempering temperatures. Cast 4300 series steels or modifications thereof are usually employed.

Mechanical Properties. Figure 4 shows typical room-temperature mechanical properties of low-alloy steels plotted against yield strength. These properties are, of course, a function of alloy content, heat treatment, and section size.

Figure 15 shows the wide range of properties obtainable through changes in carbon and alloy content and heat treatment (note the properties for 0.30% C, 1.50% Mn, and 0.35% Mo steel). Figure 16 shows the variations in mechanical properties of a water-quenched cast 8630 steel as a function of tempering temperature. Section size effects were discussed in the section "Mechanical Properties" of this article.

Fig. 15 Distribution of mechanical properties and carbon and alloy contents for alloy steel castings. (a) Cr-Mo-V steel, 1.00Cr-1.00Mo-0.25V, normalized and tempered; 25 heats. (b) Cr-Mo steel, 1.00Cr-1.00Mo, normalized and tempered; 25 heats. (c) Nickel steel, 0.20C-2.25Ni, normalized and tempered; 200 heats. (d) Mn-Mo steel, 0.30C-1.50Mn-0.35Mo, normalized and tempered; 40 heats. (e) Mn-Mo steel, 0.30C-1.50Mn-0.35Mo, quenched and tempered; 268 to 302 HB; 50 heats. (f) Mn-Mo steel, 0.30C-1.50Mn-0.35Mo, quenched and tempered; 300 to 321 HB; 50 heats

Physical Properties

The physical properties of cast steel are generally similar to those of wrought steel.

Elastic constants of carbon and low-alloy cast steels as determined at room temperature are only slightly affected by changes in composition and structure. The modulus of elasticity, E , is about 200 GPa (30×10^6 psi), Poisson's ratio is 0.3, and the modulus of rigidity is 77.2 GPa (11.2×10^6 psi). Increasing temperature has a marked effect on the modulus of elasticity and the modulus of rigidity. A typical value of the modulus of elasticity at 200 °C (400 °F) is about 193 GPa (28×10^6 psi); at 360 °C (680 °F), 179 GPa (26×10^6 psi); at 445 °C (830 °F), 165 GPa (24×10^6 psi); and at 490 °C (910 °F), 152 GPa (22×10^6 psi). Above 480 °C (900 °F), the value of the modulus of elasticity decreases rapidly.

Density of cast steel is sensitive to changes in composition, structure, and temperature. The density of medium-carbon cast steel is about 7.8 Mg/m³ (490 lb/ft³). The density of cast steel is also affected somewhat by mass or size of section (Fig. 13d).

Fig. 16 Mechanical properties of water-quenched cast 8630 steel

Electrical properties of carbon and low-alloy steel castings do not significantly affect usage. The only electrical property that may be regarded as having any importance is resistivity, which, for various annealed carbon steel castings with 0.07 to 0.20% C, is 0.13 to 0.14 $\mu\Omega \cdot m$. Resistivity increases with carbon content and is about 0.20 $\mu\Omega \cdot m$ at 1.0% C.

Magnetic Properties. Steel castings from the housings for electrical machinery and magnetic equipment and carry only stray fluxes around the machines; hence, the magnetic properties of steel castings are less important than they were formerly when core material was manufactured from commercial cast iron and steel. Low-carbon cast dynamo steel has supplanted other cast metals for housings and frames for magnetic circuits.

The carbon content of the steel is very important in determining the magnetic properties. The maximum permeability and the saturation magnetization decrease, and the coercive force increases, as the carbon content increases. Manganese, phosphorus, sulfur, and silicon also increase the magnetic hysteresis loss in cast steels. This loss is equal to about 10 J/m³ per cycle for $B = 1$ T for each 0.10% Mn, 0.01% S, and 0.01% P. Other factors being equal, the magnetic hysteresis loss is unaffected by more than 0.02% P. Magnetic properties change considerably, depending on the mechanical treatment and heat treatment of the steel.

Cast dynamo steels contain about 0.10% C, with other alloying elements held to a minimum; the castings are furnished in the annealed condition. Specifications require 0.05 to 0.15% C, 0.20% Mn, and 0.35 to 0.60 or 1.50 to 2.00% Si.

The magnetic properties of annealed cast dynamo steel that may normally be expected are:

Property	
Maximum permeability, mH/m	18.6
Hysteresis loss (induction for H)	1.91

= 11.9 kA/m), T	
Saturation magnetization, T	2.14
Residual induction, T	1.10
Coercive force, A/m	29

As the carbon content is increased, maximum permeability and saturation magnetization decrease, and coercive force increases. Also, an increase in manganese and sulfur content increase the magnetic hysteresis loss.

Silicon and aluminum eliminate the allotropic transformation in iron and permit annealing at high temperature without recrystallization during cooling; thus, large grains can be obtained. These elements can be added in large quantities without affecting magnetic properties, but they do reduce the saturation value and increase the brittleness of the metal. Hysteresis loss varies directly with grain size number; therefore, the larger the grain size, the better the properties. Residual alloy content should be low because it lowers saturation value.

The factors that improve the machinability of dynamo steel decrease the magnetic properties. A disadvantage in the use of pure iron for dynamo steel is low resistivity. The iron must be rolled thin to keep eddy currents down; otherwise, the magnetic properties will be poor.

Volumetric Changes. In the foundry, all volume changes of a metal are pertinent, whether they occur in the liquid state, during solidification, or in the solid state. Of particular interest is the contraction that results when molten steel solidifies.

Volume changes that occur in the liquid state as the cast metal cools affect the planning for adequate metal to fill the mold. Contraction is of the order of 0.9% per 100 °C (180 °F) for a 0.30% C steel. The exact amount of contraction will vary with the chemical composition, but it is usually within the range of 0.8 to 1.0% per 100 °C (180 °F) for carbon and low-alloy steels. A larger contraction occurs upon solidification (2.2% for nearly pure iron to 4% for a 1.00% C steel). For cast carbon and low-alloy steels, a solidification contraction of 3.0% is generally assumed.

The greatest amount of contraction occurs as the solidified metal cools to room temperature. Solid-state contraction from the solidus to room temperature varies between 6.9 and 7.4% as a function of carbon content. Alloying elements have no significant effect on the amount of this contraction. The rigid form of the mold hinders contraction and results in the formation of stresses within the cooling casting that may be great enough to cause fracture or hot tears in the casting. The hot metal has low strength just after solidification. The rigidity of the mold makes the proper relation of casting configuration to accommodate this contraction one of the most important factors in producing a successful casting.

In commercial production, a combination of all three contraction components may operate simultaneously. Molten metal in contact with the mold wall solidifies quickly and proceeds to solidify toward the center of the casting. The solid envelope undergoes contraction in the solid state, while a portion of the still-molten metal is solidifying. The remaining molten metal contracts as its temperature decreases toward the freezing point. Because of contraction factors, many casting designs require considerable development to produce a sound casting.

Engineering Properties

Wear Resistance. Cast steels have wear resistance comparable to that of wrought steel of similar composition and condition. Chromium leads the field as an alloying element for wear-resistant steels but is seldom used alone. Nickel-vanadium, manganese-molybdenum, and nickel-manganese cast steels are used for numerous structural purposes requiring wear resistance and high strength.

Corrosion resistance of cast steel is similar to that of wrought steel of equivalent composition. Data published on the corrosion resistance of wrought carbon and low-alloy steels under various conditions may be applied to cast steels.

Low-alloy steels are generally not considered corrosion resistant, and casting compositions are not normally selected on the basis of corrosion resistance. In some environments, however, significant differences are observed in corrosion behavior such that the corrosion rate of one steel may be half that of another grade. In general, steels alloyed with small amounts of copper tend to have somewhat lower corrosion rates than copper-free alloys. As little as 0.05% Cu has been shown to exert a significant effect. In some environments, nominal levels of nickel, chromium, phosphorus, and silicon may also bring about modest improvements, but when these four elements are present, the addition of copper holds little if any advantage. Detailed information on the corrosion resistance of steels is available in the articles "Corrosion of Carbon Steels," "Corrosion of Alloy Steels," and "Corrosion of Cast Steels" in *Corrosion*, Volume 13 of *ASM Handbook*, formerly 9th Edition *Metals Handbook*.

Soil Corrosion. Cast steel pipe has been tested for various periods up to 14 years in different types of soil. The results of these tests were compared directly with results from tests on wrought steel pipe of similar composition, and no significant difference in the corrosion of the two materials could be detected. However, the actual corrosion rate and rate of pitting of the cast pipe varied widely, depending on the soil and aeration conditions.

Elevated-Temperature Properties. Steels operating at temperatures above ambient are subject to failure by a number of mechanisms other than mechanical stress or impact. These include oxidation, hydrogen damage, sulfide scaling, and carbide instability, which manifests itself as graphitization.

The environmental factors involved in elevated-temperature service (370 to 650 °C, or 700 to 1200 °F) require that steels used in this temperature range be carefully characterized. As a consequence, four ASTM specifications have been developed for cast carbon and low-alloy steels for elevated-temperature service. One of these specifications, ASTM A 216, describes carbon steels; the other three, A 217, A 356, and A 389, cover low-alloy steels.

The two alloying elements common to nearly all the steel compositions used at elevated temperatures are molybdenum and chromium. Molybdenum contributes greatly to creep resistance. Depending on microstructure, it has been shown that 0.5% Mo reduces the creep rate of steels by a factor of at least 10^3 at 600 °C (1110 °F).

Chromium also reduces the creep rate, although modestly, at levels to approximately 2.25%. At higher chromium levels, creep resistance is somewhat reduced. Vanadium improves creep strength and is indicated in some specifications. Other elements that improve creep resistance include tungsten, titanium, and niobium. The effect of tungsten is similar to that of molybdenum, but on a weight percent basis more tungsten is required in order to be equally beneficial. Titanium and niobium have been shown to improve the creep properties of carbon-free alloys, but because they remove carbon from solid solution, their effect tends to be variable. None of the latter three elements appears in U.S. specifications for cast steels for elevated-temperature service.

Low-Temperature Toughness. In addition to the soundness, strength, and microstructure of a metal, toughness, too, is strongly affected by temperature. Steel castings suitable for low-temperature service are specified in ASTM A 352 and A 757. Figure 17 shows the effect of temperature on the impact resistance of three grades of cast steels conforming to ASTM A 352. Figure 17(b) also shows the effect of heat treatment on the impact resistance of grade LC2-1.

Fig. 17 Effect of temperature on the Charpy V-notch energy of a carbon steel and two low-alloy cast steels specified in ASTM A 352 for low-temperature service. (a) Charpy V-notch energies for a carbon cast steel, 0.30% C (max) with 1.00% Mn (max), quenched, tempered, and stress relieved, taken from a 50 × 230 × 210

mm ($2 \times 9 \times 8\frac{1}{4}$ in.) test block and from a 75 × 230 × 283 mm ($3 \times 9 \times 11\frac{1}{8}$ in.) test block. (b) Charpy V-notch energies for nickel-chromium-molybdenum cast steel specimens (taken from 50 × 230 × 210 mm, or $2 \times 9 \times 8\frac{1}{4}$ in., test block) from steel with two different tempering and aging treatments after being air cooled from 955 °C (1750 °F), reheated to 900 °C (1650 °F), and then water quenched. (c) Charpy V-notch energies for $2\frac{1}{2}$ % Ni cast steel specimens (taken from 75 × 230 × 283 mm, or $3 \times 9 \times 11\frac{1}{8}$ in., test block) after being air cooled (normalized, N) from 900 °C (1650 °F) and either tempered (T) at 620 °C (1150 °F) or reheated to 900 °C (1650 °F), water quenched (Q) and then tempered at 620 °C (1150 °F). All specimens were taken at locations greater than one-fourth the thickness in from the surface of test blocks having an ASTM grain size of 6 to 8. The curves represent average values for several tests at each test temperature.

Fracture Toughness. Figure 18 shows the effect of temperature on the fracture toughness of a carbon (0.25% C, max) cast steel specified in ASTM A 216. Table 7 shows the effect of lower temperatures on the fracture toughness of five cast steels. As described below, the fracture toughness values in Table 7 are reported in terms of either J_{Ic} or J_c when circumstances prevented the direct determination of K_{Ic} .

Fig. 18 Temperature dependence of plane-strain fracture toughness of a carbon steel casting (grade WCC of ASTM A 216). Test blocks were 508 × 508 × 1219 mm (20 × 20 × 48 in.), annealed 8 h at 900 °C (1650 °F), furnace cooled to 315 °C (600 °F), tempered 8 h at 605 °C (1125 °F), furnace cooled to 315 °C (600 °F), reheated to 955 °C (1750 °F) and held 8 h, furnace cooled to 900 °C (1650 °F), equalized, accelerated cooled to 95 °C (200 °F), final tempered 8 h at 650 °C (1200 °F), and air cooled. Compact tension specimens of three thicknesses as indicated were used. The open data points are the only symbols that indicate valid test results. Source: Ref 4

(a) Average value.

(b) Lowest value.

For cost-effective testing, the J -integral approach was used to estimate the fracture toughness of some of the steels in Table 7. The J -integral approach can be used to estimate the fracture toughness of steels having considerable elastic-plastic behavior (Ref 5) without using large specimens. Four of the steels exhibited appreciable ductility and low yield strength in smooth-specimen tensile tests, which could require that specimen thickness and crack length range from about 50 to 500 mm (2 to 20 in.) for valid K_{Ic} determinations. The larger dimensions are unreasonable for cost-effective testing. Therefore, the J -integral used to estimate fracture toughness characteristics without the use of large specimens. For linear elastic plane strain, J_{Ic} is related to K_{Ic} for linear elastic plane strain:

$$J_{Ic} = G_{Ic} = \frac{K_{Ic}^2}{E} (1 - \nu^2) \quad (\text{Eq 3})$$

where G is the strain energy release rate per unit crack extension, E is Young's modulus, and ν is Poisson's ratio.

Valid values of J_{Ic} , and hence conservative estimates of K_{Ic} , were obtained for four of the cast steels at room temperature and two cast steels at -45°C (-50°F) (Table 7). Only J_c , and hence estimates of K_c , were obtained for the other material and temperature conditions. The tests that did not produce valid J_{Ic} value were in the Charpy V-notch transition temperature energy region. Landes *et al.*, using A 471 wrought steel, showed that J_c fracture toughness values obtained in this region from small J -integral specimens had substantial scatter and that the lower limit of this J_c scatter band was similar to that of equivalent toughness measured on larger specimens (Ref 6). Landes *et al.* suggested that the lower boundary value of the J_c scatter may be reasonable to use for conservative-design criteria in the Charpy V-notch transition temperature region.

As shown in Table 7, Mn-Mo cast steel exhibited the highest fracture toughness (J_{Ic} or K_{Ic}) at both room temperature and -45°C (-50°F), while the 0050A cast steel showed the lowest fracture toughness (J_c or K_c) at both temperatures. The three martensitic cast steels (C-Mn, Mn-Mo, and 8630) had better fracture toughness at room temperature than the two ferritic-pearlitic cast steels (0030 and 0050A). The 8630 cast steel had the largest decrease in fracture toughness at -45°C (-50°F) compared to room temperature. The C-Mn and Mn-Mo steels had ductile stable crack growth and the highest J values at both room temperature and -45°C (-50°F). Based on J -integral tests, they were the best steels at both temperatures.

Machinability. Extensive lathe and drilling tests on steel castings have not revealed significant differences in the machinability of steels made by different melting processes, nor of wrought and cast steel, provided strength, hardness, and microstructure are equivalent. The skin or surface on a sand mold casting often wears down cutting tools rapidly, possibly because of adherence of abrasive mold materials to the casting. Therefore, the initial cut should be deep enough to penetrate below the skin, or the cutting speed may be reduced to 50% of that recommended for the base metal.

Microstructure has considerable effect on the machinability of cast steels. It is sometimes possible to improve the machining characteristics of a steel castings by 100% through normalizing, normalizing and tempering, or annealing.

Weldability. Steel castings have welding characteristics comparable to those of wrought steel of the same composition, and welding these castings involves the same considerations.

The severe quenching effect produced when using a small welding rod to weld a large section results in the formation of martensite in the base metal area immediately adjacent to the weld (in the heat-affected zone). This can happen even in low-carbon steel, causing loss of ductility in the heat-affected zone. Usually cast steels with a maximum of 0.20% C and 0.50% Mn present fewer problems from this effect. However, it is essential that all of the carbon steels (with more than 0.20% C) and the air-hardening alloyed steels be preheated before welding at the standard recommended temperatures, maintaining a proper interpass temperature, and then postweld heat treated to produce sufficient ductility.

To prevent cracking in carbon and low-alloy cast steels, the hardness of the weld bead should not exceed 350 HV, except where conditions are such that only compressive forces result from the welding. This value may not be low enough in configurations in which extreme restraint is involved.

Virtually all castings receive a stress-relief heat treatment after welding, even composite fabrications in which steel castings are welded to wrought steel shapes.

The maximum compositional limits that have been placed by the industry on readily weldable grades of castings are 0.35% C, 0.70% Mn, 0.30% Cr, and 0.25% Mo (max) plus W, with a total of 1.00% undesirable elements, predicated on the widespread use of stress-relief heat treatment in the steel casting industry. For each 0.01% decrease in the specified maximum carbon content, most specifications permit an increase of 0.04% Mn above the maximum specified, up to a maximum of 1.00% (ASTM A 27, grade 70-40, and A 216, grade WCC, allow up to a maximum of 1.40% Mn). Specifications for weldable grades of cast steel are ASTM A 27, A 216, A 217, A 352, A 487, and A 757. Specifications covering control of weld quality are ASTM E 164 and E 390.

Many welds that fail do not fail in the weld but in the zone immediately adjacent to the weld. While the weld is being made, this zone is heated momentarily to a melting temperature. The temperature decreases as the distance from the weld increases. Such heating induces structural changes, specifically the development of hard, brittle areas adjacent to the weld deposits, which reduce the toughness of the area and frequently cause cracking during and after cooling. Likewise, certain alloying elements other than carbon, such as nickel, molybdenum, and chromium, bring about air hardening of the base metal. For these reasons, the quantity of alloying elements to be used must be limited unless special precautions are taken, such as the preheating of the base metal to 150 to 315 °C (300 to 600 °F). Increased hardness in the heat-affected zone of the base metal can be removed by postweld heat treating the welded casting or by heating it for definite periods at 650 to 675 °C (1200 to 1250 °F). This also relieves stresses from welding.

For the arc welding of steel castings, a high-grade heavily coated electrode (AWS E7018 type), granular flux, or CO₂ atmosphere is generally desirable. These coatings contain little or no combustible material. Mineral coatings are often used to keep hydrogen absorption at a minimum and thereby limit underbead cracking. Selection of the number of passes and of welding conditions is similar to welding practice for wrought steels.

Welds in castings may be radiographed by gamma- or x-ray methods to ascertain the degree of homogeneity of the welded section. The most common imperfections are incomplete fusion, slag inclusions, and gas bubbles. Magnetic particle inspection is also useful in the detection of surface and near-surface cracks.

The mechanical properties of welds joining cast steel to cast steel and of welds joining cast steel to wrought steel are of the same order as similar welds joining wrought steel to wrought steel. Most tensile specimens machined across the weld break outside the weld, in the heat-affected zone. This does not mean that the weld is stronger than the casting base metal. Closely controlled welding techniques and stress relieving are necessary to prevent brittleness in the heat-affected zone.

Nondestructive Inspection

Highly stressed steel castings for aircraft and for high-pressure or high-temperature service must pass rigid nondestructive inspection. ASTM specifications E 186, E 280, and E446 cover radiographic standards for steel castings; E 94 covers ASTM recommended practice for radiographic testing; and E 142 covers the quality control of radiographic testing.

Radiographic acceptance standards must be agreed upon by the user and producer before production begins. Critical areas to be radiographed may be identified on the casting drawing.

Magnetic particle inspection is used on highly stressed steel castings to detect surface discontinuities or imperfections at or just below the surface. ASTM E 709 should be consulted for establishing cause for rejection before the castings are produced. The imperfections are evaluated by using ASTM E 125, "Reference Photographs for Magnetic Particle Indications on Ferrous Castings." The extent of inspection and the acceptance standards must be agreed upon by the user and producer at the time of the order.

Liquid penetrant inspection can be used on steel castings, but it is primarily used to inspect nonmagnetic materials such as nonferrous metals and austenitic steels for possible surface discontinuities. ASTM E 165 is the specification used, and E 433 gives the standard reference photographs for liquid penetrant inspection.

Ultrasonic testing is sometimes used on steel castings to detect imperfections below the surface in heavy sections that are 0.3 to 8.5 m (1 to 28 ft) thick. Test surfaces of castings should be free of material that would interfere with the ultrasonic test. These castings may be as cast, blasted, ground, or machined. The standard specification for ultrasonic testing is ASTM A 609, "Longitudinal-Beam Ultrasonic Inspection of Carbon and Low-Alloy Steel Castings." This technique is intended to complement ASTM recommended practice E 94 for the use of radiographic testing in the detection of discontinuities.

Hydrostatic testing, or pressure testing, is used on valves and castings intended to contain steam or fluids, such as those made to ASTM specifications A 216, A 217, A 352, A 356, A 389, and A 487. If a casting must pass a pressure test, essential factors must be noted on the blueprint, and the details of the test should be understood by the buyer and producer.

Bearing Steels

Harold Burrier, Jr., The Timken Company

Introduction

ROLLING-ELEMENT BEARINGS, whether ball bearings or roller bearings with spherical, straight, or tapered rollers, are fabricated from a wide variety of steels. In a broad sense, bearing steels can be divided into classes intended for normal service, high-temperature service, or service under corrosive conditions.

Bearings for normal service conditions, a category that includes over 95% of all rolling-element bearings, are applicable when:

- Maximum temperatures are of the order of 120 to 150 °C (250 to 300 °F), although brief excursions to 175 °C (350 °F) may be tolerated
- Minimum ambient temperatures are about -50 °C (-60 °F)
- The contact surfaces are lubricated with such materials as oil, grease, or mist
- The maximum Hertzian contact stresses are of the order of 2.1 to 3.1 GPa (300 to 450 ksi)

Bearings used under normal service conditions also experience the effects of vibration, shock, misalignment, debris, and handling. Therefore, the fabrication material must provide toughness, a degree of temper resistance, and microstructural stability under temperature extremes. The material must also exhibit the obvious requirement of surface hardness for wear and fatigue resistance.

Bearing Steels

Harold Burrier, Jr., The Timken Company

High-Carbon or Low-Carbon Steels

Traditionally, bearings have been manufactured from both high-carbon (1.00%) and low-carbon (0.20%) steels. The high-carbon steels are used in either a through-hardened or a surface induction-hardened condition in special integral bearing configurations, such as the automotive wheel spindle shown in Fig. 1. Low-carbon bearing steels are carburized to provide the necessary surface hardness while maintaining other desirable properties in the core.

Fig. 1 Cross-section of a surface-hardened high-carbon steel automotive spindle

The parallel development of both high- and low-carbon steels for bearing applications is rooted in history. The early European manufacturers chose to use familiar chromium-type tool steels. The American bearing manufacturers, on the other hand, added a carburized case to their soft, plain steel bearings to meet the higher hardness requirements of more highly loaded rolling-element bearings.

Both high-carbon and low-carbon materials have survived because each offers a unique combination of properties that best suits the intended service conditions. For example, high-carbon steels:

- Can carry somewhat higher contact stresses, such as those encountered in point contact loading in ball bearings
- Can be quenched and tempered, which is a simpler heat treatment than carburizing
- May offer greater dimensional stability under temperature extremes because of their characteristically lower content of retained austenite

Carburizing steels, on the other hand, offer:

- Greater surface ductility (because of their retained austenite content) to better resist the stress-raising effects of asperities, misalignment, and debris particles
- A higher level of core toughness to resist through-section fracture under severe service conditions
- A compressive residual surface stress condition to resist bending loads imposed on the ribs of roller bearings and reduce the rate of fatigue crack propagation through the cross section
- Easier machining of the base material in manufacturing

Figure 2 illustrates this last point in a comparison of tool life in machining tubing of a high-carbon steel (AISI 52100) and a carburizing steel (4320 mod) at similar hardness levels.

Fig. 2 Comparison of tool life at various cutting speeds in the machining of 52100 and 4320 steel tubing

Table 1 compares selected mechanical properties of the core material in a quenched and tempered carburizing steel with those of the unhardened portion of an induction-hardened high-carbon steel component. The values for both strength and

toughness are greater in the quenched and tempered low-carbon steel. The surface properties are largely a function of the hardness.

Table 1 Core properties of carburized versus induction-hardened components

Material	Hardness, HB	Yield strength		Ultimate tensile strength		Impact energy		Machining, % ^(a)

In rolling-contact bearings, it is essential to maintain an adequate strength throughout the region of maximum subsurface shear stresses. Figure 3 shows an estimated relationship between hardness and shear yield strength that is applicable to either steel type. The success of a given steel in a bearing application is not as much a function of the steel type as how it is treated. Fatigue resistance generally increases with hardness; the maximum depends on the steel type. Figure 4 compares the bending fatigue lives of through-carbon and carburized steels as a function of surface hardness. In bending fatigue, the combination of compressive residual surface stresses with a higher composite section toughness gives the advantage to the carburized steel.

Microstructure Characteristics

High-Carbon Bearing Steels. Figure 5 shows a typical microstructure of a hardened and tempered high-carbon bearing steel such as AISI 52100. The matrix is high-carbon martensite, containing primary carbides and 5 to 10% retained austenite. The hardness throughout the section is typically 60 to 64 HRC. Table 2 lists the compositions of selected high-carbon bearing steels currently in use. The first three grades are listed in order of increasing hardenability; they are applied to bearing sections of increasing thickness to ensure freedom from nonmartensitic transformations in hardening. Grade TBS-9 is a lower-chromium bearing steel, which, because of its residual alloy content, has a hardenability similar to that of AISI 52100. The remaining steels are representative of overseas steels applied to bearing components.

Table 2 Nominal compositions of high-carbon bearing steels

Grade	Composition, %					
	C	Mn	Si	Cr	Ni	Mo
AISI 52100	1.04	0.35	0.25	1.45
ASTM A 485-1	0.97	1.10	0.60	1.05
ASTM A 485-3	1.02	0.78	0.22	1.30	...	0.25

Fig. 5 Typical microstructure of a high-carbon through-hardened bearing component

Carburizing Bearing Steels. Figure 6 shows typical case and core microstructures of carburized bearing components. The case microstructure consists of high-carbon martensite with retained austenite in the range of 15 to 40%. Case hardness is typically 58 to 64 HRC. In the core of carburized bearings, the microstructure consists of low-carbon martensite; it also often contains variable amounts of bainite and ferrite. The core hardness may vary from 25 to 48 HRC.

Fig. 6 Typical microstructures of carburized bearing components. (a) Case. (b) Core

Table 3 lists the compositions of typical carburizing bearing steels. The AISI grades are listed in approximate order of increasing hardenability or section size applicability. SCM420 and 20MnCr5 are Japanese and German grades, respectively, found in carburized bearing components. In addition to standard AISI grades, bearing steels can also be designed so that their hardenability matches the requirements of specific section thicknesses. Alloy conservation and a more consistent heat-treating response are benefits of using specially designed bearing steels.

Table 3 Carburizing bearing steels

Grade	Compositions, %					
	C	Mn	Si	Cr	Ni	Mo
4118	0.20	0.80	0.22	0.50	...	0.11
5120	0.20	0.80	0.22	0.80
8620	0.20	0.80	0.22	0.50	0.55	0.20
4620	0.20	0.55	0.22	...	1.82	0.25
4320	0.20	0.55	0.22	0.50	1.82	0.25
3310	0.10	0.52	0.22	1.57	3.50	...
SCM420	0.20	0.72	0.25	1.05	...	0.22

The selection of a carburizing steel for a specific bearing section is based on the heat-treating practice of the producer, either direct quenching from carburizing or reheating for quenching, and on the characteristics of the quenching equipment. The importance of a proper case microstructure to the ability of a bearing to resist pitting fatigue is illustrated in Fig. 7. In particular, the presence of pearlite, resulting from a mismatch of quenching conditions and case hardenability, is shown to have a detrimental effect.

Bearing Steels

Harold Burrier, Jr., The Timken Company

Bearing Steel Quality

Apart from a satisfactory microstructure, which is obtained through the proper combination of steel grade and heat treatment, the single most important factor in achieving high levels of rolling-contact fatigue life in bearings is the cleanliness, or freedom from harmful nonmetallic inclusions, of the steel. Bearing steels can be produced by one of these techniques:

- Clean-steel air-melt practices
- Electroslag remelting
- Air melting followed by vacuum arc remelting
- Vacuum induction melting followed by vacuum arc remelting

Cleanliness, cost and reliability can increase depending on which practice is chosen.

Bearing steel cleanliness is most commonly rated by using microscopic techniques, such as those defined in ASTM A 295 for high-carbon steels and A 534 for carburizing steels. The worst fields found in metallographically prepared sections of the steel can be compared with rating charts (J-K charts) according to the type of inclusion: sulfides, stringer-type oxides, silicates, and globular-type oxides.

Table 4 lists the current levels of each of the inclusion types allowed for air-melted bearing quality steels. Several manufacturers produce bearings with significantly lower levels of nonmetallic inclusion content than allowed by rating charts.

Table 4 Nonmetallic inclusion ratings

Specification	Type A		Type B		Type C		Type D	
	Thin	Heavy	Thin	Heavy	Thin	Heavy	Thin	Heavy
ASTM A 534-76 (carburizing steel)	3.0	2.0	3.0	2.5	2.5	1.5	2.0	1.5

Bearing steel cleanliness can also be rated by oxygen analysis, the magnetic particle method (AMS 2301, AMS 2300), and ultrasonic methods. Of these, the ultrasonic method appears to show a superior correlation with bearing fatigue life when the oxygen content of the steel is less than 20 ppm. This is due to the larger volume of material sampled by the technique.

Effect of Heat Treatment

The importance of matching the hardenability and quenching of a bearing steel has been pointed out above. However, within this restriction, other heat treatment variables have been found to affect the performance of bearings, particularly under the less-than-ideal conditions of debris contamination.

Retained austenite in the microstructure is known to reduce the surface hardness of high-carbon steels, as shown in Fig. 8. The ductility of the surface, as expressed by the ratio of yield strength to fracture strength in Fig. 9, is improved by increasing amounts of retained austenite. This improved ductility often results in improved rolling-contact fatigue performance. Figure 10 illustrates this improvement by showing the results of a fatigue performance study of 14 carburizing steel compositions. The retained austenite level can be raised by adding nitrogen to the case (Fig. 11) or by increasing carburizing cycles (Fig. 12). Improved performance has been demonstrated in high-carbon steels when carburizing increased the carbon in solution and the austenite content. Figure 13 shows the improved performance of carburized AISI 52100 steel bars in comparison with uncarburized bars of the same material. Other means of increasing surface ductility, such as optimizing the austenitizing temperature (Fig. 14), controlling the quenching rate (Fig. 15), and austempering to produce a completely bainitic microstructure (Fig. 16), have been shown to improve the fatigue performance of high-carbon bearing steels for certain applications.

Special-Purpose Bearing Steels

When bearing service temperatures exceed about 150 °C (300 °F), common low-alloy steels cannot maintain the necessary surface hardness to provide satisfactory fatigue life. The low corrosion resistance of these steels makes them susceptible to attack by environmental moisture, as well as aggressive gaseous or liquid contaminants. Therefore, specialized steels are often applied when these service conditions exist.

Table 5 lists the compositions of certain bearing steels suited for high-temperature service. These steels are typically alloyed with carbide-stabilizing elements such as chromium, molybdenum, vanadium, and silicon to improve their hot hardness and temper resistance. The listed maximum operating temperatures are those at which the hardness at temperature falls below a minimum of 58 HRC. Figure 17 compares the hot hardness behavior of some high-carbon tool and bearing steels to AISI 52100 steel. Table 6 indicates the effect of extended exposure to elevated temperatures on the recovered (room-temperature) hardness of various steels, both carburized and through-hardened.

An important application of the high-temperature bearing steels is aircraft and stationary turbine engines. Bearings made from M50 steel have been used in engine applications for many years. Jet engine speeds are being continually increased

in order to improve performance and efficiency; therefore, the bearing materials used in these engines must have increased section toughness to withstand the stresses that result from higher centrifugal forces (Fig. 18). For this reason, the carburizing high-temperature bearing steels, such as M50-NiL and CBS-1000M, are receiving much attention. The core toughness of these steels is more than twice that of the through-hardening steels. Figure 19 compares the case and core fracture toughness of some of the common through-hardening and carburizing bearing steels. Figure 20 illustrates another benefit of the carburizing steels by comparing the compressive residual stress gradient present in carburized races with the tensile residual stresses found in through-hardened races. The presence of compressive residual stresses may help to retard the propagation of radial fatigue cracks through the races cross-section.

Fig. 18 Increasing section toughness of bearing materials used for jet engine applications. Fig. 19 Composite fracture toughness of carburizing and homogeneous high-carbon steels in slow bending. Case depth is 0.76 to 0.89 mm (0.030 to 0.035 in.) to 0.50% C level. Shaded areas indicate range of *K* values for cracks originating in core. Cross-hatched areas indicate range of *K* values for cracks originating in case. Charpy-sized specimens were carburized, hardened, tempered, and precracked to several depths in case and core regions before testing. As cracks progress inward, the fracture resistance of carburized composites improves significantly. Source: Ref 9

Fig. 20 Comparison of residual stresses in carburized versus through-hardened steel races. The higher residual compression of carburizing M50-NiL provides greater resistance to fracture, fatigue damage, and stress corrosion. Source: Ref 11

In general, high temperature carburizing steels require more care in the carburizing process than conventional low-alloy carburizing steels. Because of the high content of chromium and silicon in the high-temperature steels, some precarburizing treatment, such as preoxidation, is always necessary to promote satisfactory carburizing.

Bearings that require the highest corrosion resistance necessitate the use of stainless grades with greater than 12% Cr. At this time, no satisfactory carburizing technique has been developed for these grades. Thus, all corrosion-resistant bearing steels are of the through-hardening type (Table 7). Steels such as the 440C modification, CRB-7, and BG42 also offer good high-temperature hardness. Figure 21 compares the hot hardness and hardness retention properties of selected corrosion-resistant steels to those of 52100 and M50 steels.

Table 7 Corrosion-resistant bearing steels

Grade	Composition, %							
	C	Mn	Si	Cr	Mo	W	V	Nb

High-Strength Structural and High-Strength Low-Alloy Steels

Introduction

HIGH-STRENGTH carbon and low-alloy steels have yield strengths greater than 275 MPa (40 ksi) and can be more or less divided into four classifications:

- As-rolled carbon-manganese steels
- As-rolled high-strength low-alloy (HSLA) steels (which are also known as microalloyed steels)
- Heat-treated (normalized or quenched and tempered) carbon steels
- Heat-treated low-alloy steels

These four types of steels have higher yield strengths than mild carbon steel in the as-hot-rolled condition (Table 1). The heat-treated low-alloy steels and the as-rolled HSLA steels also provide lower ductile-to-brittle transition temperatures than do carbon steels (Fig. 1).

Table 1 General comparison of mild (low-carbon) steel with various high-strength steels

Steel	Chemical composition, % ^(a)				Minimum yield strength		Minimum tensile strength		Minimum ductility (elongation in 50 mm, or 2 in.), %
	C (max)	Mn	Si	Other	MPa	ksi	MPa	ksi	
Low-carbon steel	0.29	0.60-1.35	0.15-0.40	^(b)	170-250	25-36	310-415	45-60	23-30
As-hot rolled carbon-manganese steel	0.40	1.00-1.65	0.15-0.40	. . .	250-400	36-58	415-690	60-100	15-20
HSLA steel	0.08	1.30 max	0.15-0.40	0.20 Nb or 0.05 V	275-450	40-65	415-550	60-80	18-24
Heat-treated carbon steel									
Normalized ^(b)	0.36	0.90 max	0.15-0.40	. . .	200	29	415	60	24
Quenched and tempered	0.20	1.50 max	0.15-0.30	0.0005 B min	550-690	80-100	660-760	95-110	18
Quenched and tempered low-alloy steel	0.21	0.45-0.70	0.20-0.35	0.45-0.65 Mo, 0.001-0.005 B	620-690	90-100	720-800	105-115	17-18

(a) Typical compositions include 0.04% P (max) and 0.05% S (max).

(b) If copper is specified, the minimum is 0.20%.

Fig. 1 General comparison of Charpy V-notch toughness for a mild-carbon steel (ASTM A 7, now ASTM A 283, grade D), an HSLA steel, and a heat-treated constructional alloy steel

These four types of high-strength steels have some basic differences in mechanical properties and available product forms. In terms of mechanical properties, the heat-treated (quenched and tempered) low-alloy steels offer the best combination of strength (Table 1) and toughness (Fig. 1). However, these steels are available primarily as bar and plate products and only occasionally as sheet and structural shapes. In particular, structural shapes (I-beams, channels, wide-flanged beams, or special sections) can be difficult to produce in the quenched and tempered condition because shape warpage can occur during quenching. Heat treating steels is also a more involved process than the production of as-rolled steels, which is one reason the as-rolled HSLA steels are an attractive alternative. The as-rolled HSLA steels are also commonly available in all the standard wrought product forms (sheet, strip, bar, plate, and structural shapes).

This article considers four types of high-strength structural steel (which is defined here as those steels with yield strengths greater than 275 MPa, or 40 ksi): high-strength carbon steel, carbon-manganese steel, quenched and tempered low-alloy steel, and HSLA steel. Particular emphasis is placed on HSLA steels, which are an attractive alternative in structural applications because of their competitive price-per-yield strength ratios (generally, HSLA steels are priced from the base price of carbon steels but have higher yield strengths than as-rolled carbon steels). High-strength steels are used to reduce section sizes for a given design load, which allows weight savings. Reductions in section size may also be beneficial in obtaining the desired strength level during the production of structural steel. Whether steels are furnished in the as-hot-rolled or heat-treated condition, the strength levels tend to decrease as section size increases. In as-hot-rolled or normalized steel, this results from the coarser microstructure (larger grains and coarser pearlite) that develops from the slower cooling rates on the rolling mill for the thicker sections. In quenched and tempered steels, the lower strengths result because the transformation temperature increases as section thickness increases and the amount of martensite (the strongest microstructural constituent) progressively decreases. Thus, as the section size increases, it becomes more difficult to obtain the strength levels characteristic of a particular alloy.

Structural Carbon Steels

Structural carbon steels include mild steels, hot-rolled carbon-manganese steels, and heat-treated carbon steels. Mild steels and carbon-manganese steels are available in all the standard wrought forms: sheet, strip, plate, structural shapes, bar, bar-size shapes, and special sections. The heat-treated grades are available as plate, bar, and, occasionally, sheet and structural shapes.

Mild (low-carbon) steels are normally considered to have carbon contents up to 0.25% C with about 0.4 to 0.7% Mn, 0.1 to 0.5% Si, and some residuals of sulfur, phosphorus, and other elements. These steels are not deliberately strengthened by alloying elements other than carbon; they contain some manganese for sulfur stabilization and silicon for deoxidation. Mild steels are mostly used in the as-rolled, forged, or annealed condition and are seldom quenched and tempered.

The largest category of mild steels is the low-carbon (<0.08% C, with ≤0.4% Mn) mild steels used for forming and packaging. Mild steels with higher carbon and manganese contents have also been used for structural products such as plate, sheet, bar, and structural sections. Typical examples include:

Steel	Minimum yield strength	
	MPa	ksi
Hot-rolled SAE 1010 steel sheet	207	30
ASTM A 283, grade D	228	33

Before the advent of HSLA steels, these mild steels were commonly used for the structural parts of automobiles, bridges, and buildings. In automotive applications, for example, hot-rolled SAE 1010 sheet has long been used as a structural steel. However, as lighter weight automobiles became more desirable during the energy crisis, there was a trend to reduce weight by using higher-strength steels with suitable ductility for forming operations.

The trend for structural steels used in the construction of bridges and buildings has also been away from mild steels and toward HSLA steels. For many years, ASTM A 7 (now ASTM A 283, grade D) was widely used as structural steel. In about 1960, improved steelmaking methods resulted in the introduction of ASTM A 36, with improved weldability and slightly higher yield strength. Now, however, HSLA steels often provide a superior substitute for ASTM A 36, because HSLA steels provide higher yield strengths without adverse effects on weldability. Weathering HSLA steels also provide better atmospheric corrosion resistance than carbon steel.

Hot-Rolled Carbon-Manganese Structural Steels. For rolled structural plate and sections, one of the earliest approaches in achieving higher strengths involved the use of higher manganese contents. Manganese is a mild solid-solution strengthener in ferrite and is the principal strengthening element when it is present in amounts over 1% in rolled low-carbon (<0.20% C) steels. Manganese can also improve toughness properties (Fig. 2b).

Fig. 2 Effect of (a) normalizing and (b) manganese content on the Charpy V-notch impact energy of normalized carbon steels. (a) Impact energy and transition temperature of 1040 steel pipe, deoxidized with aluminum and silicon. (b) Charpy V-notch impact energy for normalized 0.30% C steels containing various amounts of manganese

Before World War II, strength in hot-rolled structural steels was achieved by the addition of carbon up to 0.4% and manganese up to 1.5%, giving yield strengths of the order of 350 to 400 MPa (50 to 58 ksi). The strengthening of these steels relies primarily on the increase in carbon content, which results in greater amounts of pearlite in the microstructure and thus higher tensile strengths. However, the high carbon contents of these steels greatly reduces notch toughness and weldability. Moreover, the increase of pearlite contents in hot-rolled carbon and alloy steels has little effect on yield strength, which, rather than tensile strength, has increasingly become the main strength criterion in structural design.

Nevertheless, carbon-manganese steels with suitable carbon contents are used in a variety of applications. Table 2 lists some high-strength carbon-manganese structural steels in the as-hot-rolled condition. If structural plate or shapes with improved toughness are required, small amounts of aluminum are added for grain refinement. Carbon-manganese steels are also used for stampings, forgings, seamless tubes, and boiler plates. Some of these steels are described according to product form in previous articles of this Volume.

Table 2 Typical compositions, tensile properties, and product sizes of high-strength structural carbon steels

(a) Product thicknesses are a maximum unless a range is given.

(b) Compositions are a maximum unless a range is given or if otherwise specified in footnotes. Residual amounts of sulfur and phosphorus are limited in all grades and have specified maximums of 0.035 to 0.04% P (max) and 0.04 to 0.05% S (max), depending on the specifications.

(c) Minimum amount of copper if specified.

(d) Over 65 mm (2.5 in.), ASTM A 738 grade A requires quenching and tempering and 1.62% Mn (max) to achieve the specified strength levels.

(e) Elongation in 50 mm (2 in.).

High-strength structural carbon steels have yield strengths greater than 275 MPa (40 ksi) and are available in various product forms:

- Cold-rolled structural sheet
- Hot-rolled carbon-manganese steels in the form of sheet, plate, bar, and structural shapes
- Heat-treated (normalized or quenched and tempered) carbon steels in the form of plate, bar, and occasionally, sheet and structural shapes

This section focuses on the heat-treated carbon structural steels, which typically attain yield strengths of 290 to 690 MPa (42 to 100 ksi). Cold-rolled carbon steel sheet with yield strengths greater than 275 MPa (40 ksi) are discussed in the article "Carbon and Low-Alloy Steel Sheet and Strip" in this Volume. High-strength carbon-manganese steels in the as-hot-rolled condition are discussed in the previous section of this article.

The heat treatment of carbon steels consists of either normalizing or quenching and tempering. These heat treatments can be used to improve the mechanical properties of structural plate, bar, and occasionally, structural shapes. Structural shapes (such as I-beams, channels, wide-flange beams, and special sections) are primarily used in the as-hot-rolled

condition because warpage is difficult to prevent during heat treatment. Nevertheless, some normalized or quenched and tempered structural sections can be produced in a limited number of section sizes by some manufacturers.

Normalizing involves air cooling from austenitizing temperatures and produces essentially the same ferrite-pearlite microstructure as that of hot-rolled carbon steel, except that the heat treatment produces a finer grain size. This grain refinement makes the steel stronger, tougher, and more uniform throughout. Typical product forms and tensile properties of normalized carbon structural steels are given in Table 2. Charpy V-notch impact energies at various temperatures are given in Fig. 2(b) for a normalized carbon steel with varying manganese contents.

Quenching and tempering, that is, heating to about 900 °C (1650 °F), water quenching, and tempering at temperatures of 480 to 600 °C (900 to 1100 °F) or higher, can provide a tempered martensitic or bainitic microstructure that results in better combinations of strength and toughness. An increase in the carbon content to about 0.5%, usually accompanied by an increase in manganese, allows the steels to be used in the quenched and tempered condition. For quenched and tempered carbon-manganese steels with carbon contents up to about 0.25% (Table 2), low hardenability restricts the section sizes to about 150 mm (6 in.).

The yield strength of quenched and tempered carbon-manganese steel plate varies from 315 to 550 MPa (46 to 80 ksi), depending on section thickness (Table 2). Minimum Charpy V-notch impact toughness may be as high as 27 to 34 J (20 to 25 ft · lbf) at temperatures as low as -68 °C (-90 °F) for quenched and tempered carbon steel having yield strengths of 345 MPa (50 ksi). However, for quenched and tempered carbon steel with 690 MPa (100 ksi) yield strengths (Table 1), the impact values are lower, normally about 20 J (15 ft · lbf) at -60 °C (-75 °F). All grades can be grain refined with aluminum to improve toughness.

In addition to high-strength plate applications, quenched and tempered carbon-manganese steels are used for shafts and couplings. Steels with 0.40 to 0.60% C are used for railway wheels, tires, and axles, while those with higher carbon contents can be used as high-strength wire laminated spring materials, often with silicon-manganese or chromium-vanadium additions. The higher-carbon steels are also used for rails (0.7% C) and, over a range of carbon contents (typically, 0.20-0.50% C), for reinforcing bar.

High-Strength Structural and High-Strength Low-Alloy Steels

Quenched and Tempered Low-Alloy Steel

Alloy steels are defined as those steels that: (1) contain manganese, silicon, or copper in quantities greater than the maximum limits (1.65% Mn, 0.60% Si, and 0.60% Cu) of carbon steel; or (2) that have specified ranges or minimums for one or more other alloying additions. The low-alloy steels are those steels containing alloy elements, including carbon, up to a total alloy content of about 8.0%.

Except for plain carbon steels that are microalloyed with just vanadium, niobium, and/or titanium (see the section "Microalloyed Quenched and Tempered Grades" in this article), most low-alloy steels are suitable as engineering quenched and tempered steels and are generally heat treated for engineering use. Low-alloy steels with suitable alloy compositions have greater hardenability than structural carbon steel and, thus, can provide high strength and good toughness in thicker sections by heat treatment. Their alloy contents may also provide improved heat and corrosion resistance. However, as the alloy contents increase, alloy steels become more expensive and more difficult to weld. Quenched and tempered structural steels are primarily available in the form of plate or bar products.

Alloying Elements and Their Effect on Hardenability and Tempering. Quenched and tempered steels have carbon contents in the range of 0.10 to 0.45%, with alloy contents, either singly or in combination, of up to 1.5% Mn, 5% Ni, 3% Cr, 1% Mo, 0.5% V, 0.10% Nb; in some cases they contain small additions of titanium, zirconium and/or boron. Generally the higher the alloy content, the greater the hardenability, and the higher the carbon content, the greater the available strength. Some typical compositions of quenched and tempered low-alloy steel plate are shown in Table 3. The response to heat treatment is the most important function of the alloying elements in these steels.

Table 3 Typical compositions of quenched and tempered low-alloy steel plate

Additional grades can be found in the article "Carbon and Low-Alloy Steel Plate" in this Volume.

(a) When a single value is shown, it is a maximum limit.

(b) Vanadium may be substituted for part or all of the titanium content on a one-for-one basis.

(c) Limiting values vary with plate thickness.

(d) Minimum when specified.

(e) Niobium may be present in ASTM A 678, grade D, in the amount of 0.01 to 0.05%.

Steel on Hardenability. The hardenability of a steel is the property that determines the depth and distribution of martensite induced by quenching. It is usually the single most important criterion for selecting a low-alloy steel. To ensure adequate hardenability, the alloys must be in solution in austenite so that they retard the diffusion-controlled transformation of austenite to ferrite-pearlite. This allows the slower cooling of a piece or the quenching of a larger piece in a given medium without subsequent transformation of austenite to undesirable ferrite-pearlite transformation products.

Hardenability is measured in terms of an ideal diameter (D_I), which facilitates the comparison of the hardening response of different steels to the same quenching medium. The ideal diameter, D_I , is affected by austenite grain size, carbon content, and alloy content; an increase in any of these factors reduces or eliminates diffusion-controlled transformations, thereby encouraging the formation of martensite. Carbon is the most potent alloy for increasing hardenability, but it can be undesirable in structural steels because of its adverse effects on weldability and toughness. The other two factors, grain size and alloy elements, are considered below and in the article "Hardenability of Carbon and Low-Alloy Steels" in this Volume.

Austenite grain size influences not only hardenability but also strength and toughness. Increases in austenite grain size reduce the strength of a given transformation product (see Fig. 3(b) for martensitic transformation products, for example), but these increases do allow hardening to a greater depth than fine-grained steels, all other factors being equal. For steels in which pearlite (or ferrite) limits the hardenability of the steel, a useful diagram relating grain size (ASTM grain size number) to ideal critical diameter (D_I) in steels was developed by Grossmann in 1952 and is shown in Fig. 3(a). For such steels, the influence of grain size can be considered independent of the steel composition. For alloy steels in which bainite, rather than pearlite, is the dominant structure limiting full hardening, the effect of austenitic grain size is not the same. Low-carbon (0.06%) bainites may not be greatly affected by prior-austenite grain size. Although a larger grain size improves hardenability, increases in grain size increase the possibility of quench cracking. The small effect of prior-austenite grain size on the strength of martensite is shown in Fig. 3(b) for two alloy steels. Larger grain size can also degrade toughness, although avoiding proeutectoid ferrite is the overriding concern in the maintenance of notch toughness.

Fig. 3(a) Diagram showing direct relationship between ASTM grain size number and hardenability. For a grain size increment of one ASTM grain size number, multiply by 1.083. For a grain size increase of two ASTM size numbers, multiply by 1.172. For an increased grain size of three ASTM size numbers, multiply by 1.270. Source: Ref 1

Fig. 3(b) Effect of prior-austenite grain size on the strength of martensite. Source: Ref 2

The effect of alloying elements on hardenability was shown by Grossmann in 1942 to be a multiplicative effect rather than an additive effect. During subsequent research, multiplying factors were developed with the realization that at times interaction effects occurred (that is, the multiplying factor for a given percentage of an element was not the same when added in conjunction with another element as it was when the element was used alone). For example, the multiplying factor for molybdenum varies with nickel content (Fig. 4). Also, there is a different set of multiplying factors for low-carbon alloys than for medium-carbon alloys. Because of this, Fig. 4 provides multiplying factors for steels having carbon contents similar to those shown in Table 3.

Fig. 4 Average multiplying factors for several elements in alloy steels containing 0.15 to 0.25% C. Source: Ref 1

Some other interaction effects of alloying elements on hardenability are shown in Table 4. In general, alloying elements can be separated according to whether they are austenite stabilizers, such as manganese, nickel, and copper, or ferrite stabilizers (for example, γ -loop formers), such as molybdenum, silicon, titanium, vanadium, zirconium, tungsten, and niobium (Ref 4). Ferrite stabilizers require a much lower alloying addition than the austenite stabilizers for an equivalent increase in hardenability. However, with many of these ferrite stabilizers the competing process of carbide precipitation in the austenite depletes the austenite of both carbon and alloy addition, thus lowering hardenability. The precipitates also produce grain refinement, which further decreases hardenability.

Table 4 Effects of alloy elements on the heat treatment of quenched and tempered alloy steels

Effect of alloy on hardenability during quenching	Effect of alloy on tempering
Manganese contributes markedly to hardenability, especially in amounts greater than 0.8%. The effect of manganese up to 1.0% is stronger in low- and high-carbon steels than in medium-carbon steels.	Manganese increases the hardness of tempered martensite by retarding the coalescence of carbides, which prevent grain growth in the ferrite matrix. These effects cause a substantial increase in the hardness of tempered martensite as the percentage of manganese in the steel increases.
Nickel is similar to manganese at low alloy additions, but is less potent at the high alloy levels. Nickel is also affected by carbon content, the medium-carbon steels having the greatest effect. There is an alloy interaction between manganese and nickel that must be taken into account at lower austenitizing temperatures.	Nickel has a relatively small effect on the hardness of tempered martensite, which is essentially the same at all tempering temperatures. Because nickel is not a carbide former, its influence is considered to be due to a weak solid-solution strengthening.
Copper is usually added to alloy steels for its contribution to atmospheric-corrosion resistance and at higher levels for precipitation hardening. The effect of copper on hardenability is similar to that of nickel, and in hardenability calculations it has been suggested that the sum of copper plus nickel be used with the appropriate multiplying factor of nickel.	Copper is precipitated out when steel is heated to about 425-650 °C (800-1200 °F) and thus can provide a degree of precipitation hardening.
Silicon is more effective than manganese at low alloy levels and has a strengthening effect on low-alloy steels. However, at levels greater than 1% this element is much less effective than manganese. The effect of silicon also varies considerably with carbon content and other alloys present. Silicon is relatively ineffective in low-carbon steel but is very effective in high-carbon steels.	Silicon increases the hardness of tempered martensite at all tempering temperatures. Silicon also has a substantial retarding effect on softening at 316 °C (600 °F), and has been attributed to the inhibiting effect of silicon on the conversion of ϵ-carbide to cementite^(a).
Molybdenum is most effective in improving hardenability. Molybdenum has a much greater effect in high-carbon steels than in medium-carbon steels. The presence of chromium decreases the multiplying factor, whereas the presence of nickel enhances the hardenability effect of molybdenum ^(b) .	Molybdenum retards the softening of martensite at all tempering temperatures. Above 540 °C (1000 °F), molybdenum partitions to the carbide phase and thus keeps the carbide particles small and numerous. In addition, molybdenum reduces susceptibility to tempering embrittlement.
Chromium behaves much like molybdenum and has its greatest effect in medium-carbon steels. In low-carbon steel and carburized steel, the effect is less than in medium-carbon steels, but is still significant. As a result of the stability of chromium carbide at lower austenitizing temperatures, chromium becomes less effective.	Chromium, like molybdenum, is a strong carbide-forming element that can be expected to retard the softening of martensite at all temperatures. Also, by substituting chromium for some of the iron in cementite, the coalescence of carbides is retarded.
Vanadium is usually not added for hardenability in quenched and tempered structural steels (such as ASTM A 678, grade D) but is added to provide secondary hardening during tempering. Vanadium is a strong carbide former, and the steel must be austenitized at a sufficiently high temperature and for a sufficient length of time to ensure that the vanadium is in solution and thus able to contribute to hardenability. Moreover, solution is possible only if small amounts of vanadium are added ^(c) .	Vanadium is a stronger carbide former than molybdenum and chromium and can therefore be expected to have a much more potent effect at equivalent alloy levels. The strong effect of vanadium is probably due to the formation of an alloy carbide that replaces cementite-type carbides at high tempering temperatures and persists as a fine dispersion up to the A_1 temperature.
Tungsten has been found to be more effective in high-carbon steels than in steels of low carbon content (less than 0.5%). Alloy interaction is important in tungsten-containing steels, with manganese-molybdenum-chromium having a greater effect on the	Tungsten is also a carbide former and behaves like molybdenum in simple steels. Tungsten has been proposed as a substitute for molybdenum in reduced-activation ferritic steels for nuclear applications^(d).

<p>multiplying factors than silicon or nickel additions.</p>	
<p>Titanium, niobium, and zirconium are all strong carbide formers and are usually not added to enhance hardenability for the same reasons given for vanadium. In addition, titanium and zirconium are strong nitride formers, a characteristic that affects their solubility in austenite and hence their contribution to hardenability.</p>	<p>Titanium, niobium, and zirconium should behave like vanadium because they are strong carbide formers.</p>
<p>Boron can considerably improve hardenability, the effect varying notably with the carbon content of the steel. The full effect of boron on hardenability is obtained only in fully deoxidized (aluminum-killed) steels.</p>	<p>Boron has no effect on the tempering characteristics of martensite, but a detrimental effect on toughness can result from the transformation to nonmartensitic products.</p>

Effects of Tempering. Because the hard martensite produced after quenching is also extremely brittle, virtually all hardened steels undergo a subcritical heat treatment referred to as tempering. Tempering improves the toughness of the as-quenched martensite, but also softens the steel, thus causing a decrease in strength and an increase in ductility. This softening is largely due to the rapid coarsening of cementite (Fe_3C) with increasing tempering temperature and a reduction in dislocation density.

Alloying elements can help retard the degree of softening during tempering, and certain elements are more effective than others. The alloys that act as solid-solution strengtheners (nickel, silicon, aluminum, and manganese) remain dissolved in the martensite and do not significantly retard the softening effect, although silicon (Table 4) does retard softening by inhibiting the coarsening of iron carbide (Fe_3C). The most effective elements in retarding the rate of softening during tempering are the strong carbide-forming elements such as molybdenum, chromium, vanadium, niobium, and titanium (Table 4). The metal carbides produced from these elements are harder than martensite (Fig. 5) and have a fine dispersion because the diffusion of the carbide-forming elements is more sluggish than the diffusion of carbon. The lower diffusion rate of the carbide-forming elements inhibits the coarsening of Fe_3C and thus retards the rate of softening at elevated temperatures.

Fig. 5 Hardness of martensite and various carbides in an M2 tool steel. Representative analyses of carbide

compositions are shown in the accompanying table. Source: Ref 5

The formation of carbides, which is a diffusion-controlled process dependent upon the migration of the carbide-forming elements, can reduce the rate of softening at all tempering temperatures. The degree of softening also depends on the quantity of the carbide-forming element. Figure 6, for example, shows reductions in softening at all tempering temperatures with various amounts of molybdenum. Similar effects occur for other carbide-forming elements, with the retardation in softening depending upon the type of carbide formed. In Fig. 5, for example, the maximum hardness obtainable in martensite is compared with the range of hardness for metal carbides (MC , M_2C , M_6C , M_3C and $M_{23}C$), with representative analyses of carbide compositions shown in the table accompanying Fig. 5. In this case, the hardest carbide in steel, MC , is predominately a carbide of vanadium. The M_2C is a carbide of tungsten and molybdenum, and some vanadium.

Fig. 6 Retardation of softening and secondary hardening during the tempering of a 0.35% C steel with various additions of molybdenum. Source: Ref 6

If the carbide-forming elements are present in sufficient quantity, the metal carbides not only reduce softening but also produce a hardness increase at the higher tempering temperature (Fig. 6). This hardness increase is frequently referred to as secondary hardening. Given a sufficient level of carbide-forming elements, secondary hardening depends on a high enough temperature to allow a sufficient diffusion rate of the carbide-forming elements. Moreover, because the diffusion of the carbide formers is a more sluggish process than carbon diffusion, the metal carbides formed have a fine dispersion and are very resistant to coarsening. The latter characteristic of the fine metal carbides provides good creep resistance and is used to advantage in steels that must not soften during elevated-temperature exposure. See the articles "Wrought Tool Steels" and "Elevated-Temperature Properties of Ferritic Steels" in this Volume for additional information on secondary hardening steels with additions of molybdenum, vanadium, chromium, tungsten, and/or other carbide-forming elements.

Microalloyed Quenched and Tempered Grades. Although fittings with 0.6% Mn and induction bends use quenching and tempering as a standard practice, mild steels (plain, low-carbon steels with less than 0.7% Mn) with microalloying additions of vanadium, niobium, or titanium are seldom used as quenched and tempered steels. However, elements such as boron and vanadium are considered as substitutes for other elements that enhance hardenability. For example, the high cost of molybdenum in the late 1970s prompted considerable research in an effort to partially or completely replace molybdenum with microadditions of vanadium or of vanadium plus titanium (Ref 7, 8, 9, 10). The titanium was added in order to form titanium nitride, thereby retaining an increased amount of vanadium in solution. This provided for a more efficient use of vanadium as a hardenability agent.

In terms of hardenability, the basic difficulty with vanadium (and other strong carbide formers such as titanium, niobium, and zirconium) is that the hardenability of steel can be increased only if small amounts are added and if the steel is austenitized at a high enough temperature and for a long enough time to ensure that the vanadium (or other strong carbide former) is in solution. Opinions vary as to the practical maximum amount of vanadium that can be added while still avoiding the nucleating effect of undissolved vanadium carbides, which would reduce hardenability. Complete solubility of vanadium during austenitization may not be the only factor in raising hardenability (Ref 11). The interaction of vanadium with other elements and the stabilization of nitrogen (with titanium) also influence hardenability. For example, Sandberg *et al.* (Ref 9, 10) investigated completely V-substituted variants of 4140-base series (0.4C-1Cr) with titanium additions, as well as partially V-substituted variants with and without titanium additions. The study concluded that:

- Complete substitution of molybdenum by vanadium does not increase the hardenability over standard 4140 (0.20% Mo) even when all the vanadium is dissolved during austenitization
- Steels containing 0.1 to 0.2% V and 0.04% Ti are characterized by significantly increased hardenability (10 to 25% in D_I) over standard 4140
- Microalloy combinations of V + Mo + Ti (~0.06-0.06-0.04%) provide very high hardenability, with D_I being up to 60% greater than the D_I in standard 4140 with 0.20% Mo. This effect is completely absent in a partially substituted steel without titanium (or aluminum as discussed below)

With regard to the third observation, however, Manganon (Ref 7, 8) has reported that for 4330-base steel (0.3C-0.5Cr-1.9Ni), 0.15% V (without titanium) can be substituted for 0.3% Mo without detriment to hardenability (although at present, complete substitution is more expensive because the price of molybdenum is much lower than that of vanadium). Nevertheless, there also exists a synergism between molybdenum and vanadium such that the hardenability of a steel containing 0.15% V and 0.10% Mo is considerably superior to that of standard 4330 with 0.3% Mo. Additions of titanium to this partially substituted steel produced a further marginal increase in hardenability. Niobium also produces a niobium-molybdenum synergy in quenched and tempered steels; niobium can be present in amounts up to about 0.04% Nb without a decrease in the hardenability of carbon steels.

The pronounced effect on hardenability of molybdenum-vanadium combinations without titanium as observed by Manganon (Ref 7, 8) in 4330 steels, can probably be reconciled with the third result of Sandberg *et al.*, in that the latter studied steels containing 0.06% Al, which would be expected to remove nitrogen to about the same extent as 0.04% Ti. Because small amounts of dissolved nitrogen promote the formation of VN (which removes vanadium from solution and thus detracts from the effectiveness of vanadium as a hardenability raiser), dissolved nitrogen must be limited via the presence of titanium or excess aluminum. By tying up the nitrogen as TiN or AlN, the vanadium can be in solution and thus increase hardenability.

Mechanical Properties. Quenched and tempered alloy steels can offer a combination of high strength and good toughness. Table 5 lists some typical tensile properties of the low-alloy plate steels given in Table 3. Figure 1 compares the low-temperature impact toughness of a heat-treated alloy steel with the impact toughness of a mild steel (ASTM A 7, which is now ASTM A 283, grade D) and an HSLA steel.

Table 5 Minimum tensile properties and maximum plate thickness for the quenched and tempered low-alloy steels listed in Table 3

(a) Maximum plate thickness for the specified mechanical properties when a single value is shown.

(b) Maximum plate thickness is not defined in ASTM A 543; plates in ASTM A 543 are intended for applications requiring plate thicknesses of 50 mm (2 in.) or more.

In addition, quenched and tempered alloy steel plate is available with ultrahigh strengths and enhanced toughness. Ultrahigh-strength steels with yield strengths above 1380 MPa (200 ksi) are described in the article "Ultrahigh-Strength Steels" in this Volume. Also within the category of ultrahigh-strength quenched and tempered steels is ball and roller bearing steel (see the article "Bearing Steels" in this Volume).

Enhanced toughness and high strength are achieved in the nickel-chromium-molybdenum alloys, which include steels such as ASTM A 543, HY-80, HY-100, and HY-130 (Table 3). These steels use nickel to improve toughness. The Charpy V-notch impact energies of the HY-80 and HY-100 grades are shown in Table 6. Figure 7 shows the Charpy V-notch impact energies of HY-130 at various temperatures.

Table 6 Charpy V-notch impact strengths of two nickel-chromium-molybdenum steels

High-Nickel Steels for Low-Temperature Service. For applications involving exposure to temperatures from 0 to -195 °C (32 to -320 °F), the ferritic steels with high nickel contents are typically used. Such applications include storage tanks for liquefied hydrocarbon gases and structures and machinery designed for use in cold regions. Properties of steels at low temperatures are discussed in the article "Low-Temperature Properties of Structural Steels" in this Volume.

The steels considered for the above applications also include the HY-130 steel in Table 3 and the various steels shown in Table 7. These steels utilize the effect of nickel content in reducing the impact transition temperature, thereby improving toughness at low temperatures. Carbon and alloy steel castings for subzero-temperature service are covered by ASTM standard specification A 757.

Table 7 Compositions of ferritic nickel steel plate for use at subzero temperatures

A 553 II	0.13	0.90	0.035	0.040	0.15-0.30	7.5-8.5

(a) Single values are maximum limits.

The 5% Ni alloys for low-temperature service include HY-130 in Table 3 and ASTM A 645 in Table 7. Typical Charpy V-notch impact energies of HY-130 at low temperatures are shown in Fig. 7. For steel purchased according to ASTM A 645, minimum Charpy V-notch impact requirements for 25 mm (1 in.) plate are designated at -170 °C (-275 °F) for hardened, tempered, and reversion-annealed plate. Minimum impact energies at this temperature range from 5 J (4 ft · lbf) for a 10 × 2.50 mm (0.4 × 0.1 in.) transverse specimen to 22 J (16 ft · lbf) for a 10 × 10 mm (0.4 × 0.4 in.) transverse specimen.

Double normalized and tempered 9% nickel steel is covered by ASTM A 353, and quenched and tempered 8% and 9% nickel steels are covered by ASTM A 553 (types I and II). For quenched and tempered material, the minimum lateral expansion in Charpy V-notch impact tests is 0.38 mm (0.015 in.). Charpy tests on 9% Ni steel (type I) are conducted at -195 °C (-320 °F); tests on 8% Ni steel (type II) are conducted at -170 °C (-275 °F). The transverse Charpy V-notch impact energies must not be less than 27 J (20 ft · lbf) at the specified temperature. Each impact test value must constitute the average value of three specimens, with not more than one value being below the specified minimum value of 27 J (20 ft · lbf) and no value being below 20 J (15 ft · lbf) for full-size specimens. Longitudinal Charpy impact properties must not be less than 34 J (25 ft · lbf) at the specified temperatures.

Typical tensile properties of 5% and 9% Ni steels at room temperature and at subzero temperatures are presented in Table 8. Yield and tensile strengths increase as testing temperature is decreased. These steels remain ductile at the lowest testing temperatures.

Table 8 Typical tensile properties of ferritic nickel steels at low temperatures

(b) Double normalized and tempered: held at 900 °C (1650 °F) 1 h for each 25 mm (1 in.) of thickness, air cooled; 790 °C (1450 °F) 1 h for each 25 mm (1 in.) of thickness, air cooled; held at 570 °C (1050 °F) for 1 h for each 25 mm (1 in.) of thickness, air cooled or water quenched.

(c) Quenched and tempered: 800 °C (1475 °F), water quenched; 570 °C (1050 °F) for 30 min for each 25 mm (1 in.) of thickness, air cooled or water quenched.

Ferritic nickel steels are too tough at room temperature for valid fracture toughness (K_{Ic}) data to be obtained on specimens of reasonable size, but limited fracture toughness data have been obtained on these steels at subzero temperatures by the J-integral method. Results of these tests are presented in Table 9. The 5% Ni steel retains relatively high fracture toughness at -162 °C (-260 °F), and the 9% Ni steel retains relatively high fracture toughness at -196 °C (-320 °F). These temperatures approximate the minimum temperatures at which these steels may be used.

Table 9 Fracture toughness of 5% and 9% Ni steel plate for compact tension specimens in transverse or longitudinal orientation

High-Strength Structural and High-Strength Low-Alloy Steels

HSLA Steels

High-strength low-alloy (HSLA) steels are a group of low-carbon steels that utilize small amounts of alloying elements to attain yield strengths greater than 275 MPa (40 ksi) in the as-rolled or normalized condition. These steels have better mechanical properties and sometimes better corrosion resistance than as-rolled carbon steels. Moreover, because the higher strength of HSLA steels can be obtained at lower carbon contents, the weldability of many HSLA steels is comparable to or better than that of mild steel (Ref 21).

High-strength low-alloy steels are primarily hot-rolled into the usual wrought product forms (sheet, strip, bar, plate, and structural sections) and are commonly furnished in the as-hot-rolled condition. However, the production of hot-rolled HSLA products may also involve special hot-mill processing that further improves the mechanical properties of some HSLA steels and product forms. These processing methods include:

- *The controlled rolling* of precipitation-strengthened HSLA steels to obtain fine austenite grains and/or highly deformed (pancaked) austenite grains, which during cooling transform into fine ferrite grains that greatly enhance toughness while improving yield strength
- *The accelerated cooling* of, preferably, controlled-rolled HSLA steels to produce fine ferrite grains during the transformation of austenite. These cooling rates cannot be rapid enough to form acicular ferrite, nor can they be slow enough so that high coiling temperatures result and thereby causing the overaging of precipitates
- *The quenching or accelerated air or water cooling* of low-carbon steels ($\leq 0.08\%$ C) that possess adequate hardenability to transform into low-carbon bainite (acicular ferrite). This microstructure offers an excellent combination of high yield strengths (275 to 690 MPa, or 60 to 100 ksi), excellent weldability and formability, and high toughness (controlled rolling is necessary for low ductile-brittle transition temperatures)
- *The normalizing* of vanadium-containing HSLA steels to refine grain size, thereby improving toughness and yield strength
- *The intercritical annealing* of HSLA steels (and also carbon-manganese steels with low carbon contents) to obtain a dual-phase microstructure (martensite islands dispersed in a ferrite matrix). This microstructure exhibits a lower yield strength but, because of rapid work-hardening capability, provides a better combination of ductility and tensile strength than conventional HSLA steels (Fig. 8) and improved formability

The usefulness and cost effectiveness of these processing methods are highly dependent on product form and alloy content, which are considered in more detail in the following sections.

(a)

(b)

(c)

(b) Strength-elongation relationships for various cold-rolled sheet steels. (c) Deep-drawing properties of steel sheet grades. Source: Ref 21

In addition to hot-rolled products, HSLA steels are also furnished as cold-rolled sheet and forgings. Cold-rolled HSLA sheet and HSLA forgings are discussed in the section "Applications of HSLA Steels" in this article. HSLA forgings are also covered in the article "High-Strength Low-Alloy Steel Forgings" in this Volume. The main advantage of HSLA forgings (like as-hot-rolled HSLA products) is that yield strengths in the range of 275 to 485 MPa (40 to 70 ksi) or perhaps higher can be achieved without heat treatment. Base compositions of these microalloyed ferrite-pearlite forgings are typically 0.3-0.50% C and 1.4-1.6% Mn. Low-carbon bainitic HSLA steel forgings have also been developed.

HSLA Steel Categories and Specifications

High-strength low-alloy steels include many standard and proprietary grades designed to provide specific desirable combinations of properties such as strength, toughness, formability, weldability, and atmospheric-corrosion resistance. These steels are not considered alloy steels, even though their desired properties are achieved by the use of small alloy additions. Instead, HSLA steels are classified as a separate steel category, which is similar to as-rolled mild-carbon steel with enhanced mechanical properties obtained by the judicious (small) addition of alloys and, perhaps, special processing techniques such as controlled rolling. This separate product recognition of HSLA steels is reflected by the fact that HSLA steels are generally priced from the base price for carbon steels, not from the base price for alloy steels. Moreover, HSLA steels are often sold on the basis of minimum mechanical properties, with the specific alloy content left to the discretion of the steel producer.

Although HSLA steels are available in numerous standard and proprietary grades (see, for example, the listing of over 600 HSLA steels in Ref 23), HSLA steels can be divided into six categories:

- *Weathering steels*, which contain small amounts of alloying elements such as copper and phosphorus for improved atmospheric corrosion resistance and solid-solution strengthening
- *Microalloyed ferrite-pearlite steels*, which contain very small (generally, less than 0.10%) additions of strong carbide or carbonitride-forming elements such as niobium, vanadium, and/or titanium for precipitation strengthening, grain refinement, and possibly transformation temperature control
- *As-rolled pearlitic steels*, which may include carbon-manganese steels but which may also have small additions of other alloying elements to enhance strength, toughness, formability, and weldability
- *Acicular ferrite (low-carbon bainite) steels*, which are low-carbon (<0.08% C) steels with an excellent combination of high yield strengths, weldability, formability, and good toughness
- *Dual-phase steels*, which have a microstructure of martensite dispersed in a ferritic matrix and provide a good combination of ductility and high tensile strength (Fig. 8)
- *Inclusion shape controlled steels*, which provide improved ductility and through-thickness toughness by the small additions of calcium, zirconium, or titanium, or perhaps rare-earth elements so that the shape of the sulfide inclusions are changed from elongated stringers to small, dispersed, almost spherical globules
- *Hydrogen-induced cracking resistant steels* with low carbon, low sulfur, inclusion shape control, and limited manganese segregation, plus copper contents greater than 0.26%

These seven categories are not necessarily distinct groupings, in that an HSLA steel may have characteristics from more than one grouping. For example, all the above types of steels can be inclusion shape controlled. Microalloyed ferrite-pearlite steel may also have additional alloys for corrosion resistance and solid-solution strengthening. A separate category might also be considered for the HSLA 80 (Navy) nickel-copper-niobium steel (0.04% C, 1.5% Mn, 0.03% Nb, 1.0% Ni, 1.0% Cu, and 0.7% Cr). Table 10 describes some typical HSLA steels, their available mill forms, and their intended applications.

Table 10 Summary of characteristics and intended uses of HSLA steels described in ASTM specifications

ASTM specifications ^(a)	Title	Alloying elements ^(b)	Available mill forms	Special characteristics	Intended uses
A 242	High-strength low-alloy structural steel	Cr, Cu, N, Ni, Si, Ti, V, Zr	Plate, bar, and shapes ≤ 100 mm (4 in.) in thickness	Atmospheric-corrosion resistance four times that of carbon steel	Structural members in welded, bolted, or riveted constructions
A 572	High-strength low-alloy niobium-vanadium steels of structural quality	Nb, V, N	Plate, bar, shapes, and sheet piling ≤ 150 mm (6 in.) in thickness	Yield strengths of 290 to 450 MPa (42 to 65 ksi), in six grades	Welded, bolted, or riveted structures, but mainly bolted or riveted bridges and buildings
A 588	High-strength low-alloy structural steel with 345 MPa (50 ksi) minimum yield point ≤ 100 mm (4 in.) in thickness	Nb, V, Cr, Ni, Mo, Cu, Si, Ti, Zr	Plate, bar, and shapes ≤ 200 mm (8 in.) in thickness	Atmospheric-corrosion resistance four times that of carbon steel; nine grades of similar strength	Welded, bolted, or riveted structures, but primarily welded bridges and buildings in which weight savings or added durability is important
A 606	Steel sheet and strip, hot rolled and cold rolled, high strength low alloy with improved corrosion resistance	Not specified	Hot-rolled and cold-rolled sheet and strip	Atmospheric-corrosion resistance twice that of carbon steel (type 2) or four times that of carbon steel (type 4)	Structural and miscellaneous purposes for which weight savings or added durability is important
A 607	Steel sheet and strip, hot rolled and cold rolled, high strength low alloy niobium and/or vanadium	Nb, V, N, Cu	Hot-rolled and cold-rolled sheet and strip	Atmospheric-corrosion resistance twice that of carbon steel, but only when copper content is specified; yield strengths of 310 to 485 MPa (45 to 70 ksi) in six grades	Structural and miscellaneous purposes for which greater strength or weight savings is important
A 618	Hot-formed welded and seamless high-strength low-alloy structural tubing	Nb, V, Si, Cu	Square, rectangular, round, and special-shape structural welded or seamless tubing	Three grades of similar yield strength; may be purchased with atmospheric-corrosion resistance twice that of carbon steel	General structural purposes, included welded, bolted, or riveted bridges and buildings
A 633	Normalized high-strength low-alloy structural steel	Nb, V, Cr, Ni, Mo, Cu, N, Si	Plate, bar, and shapes ≤ 150 mm (6 in.) in thickness	Enhanced notch toughness; yield strengths of 290 to 415 MPa (42 to 60 ksi) in five grades	Welded, bolted, or riveted structures for service at temperatures ≥ -45 °C (-50 °F)
A 656	High-strength, low-alloy, hot-rolled structural vanadium-aluminum-nitrogen and	V, Al, N, Ti, Si	Plate, normally ≤ 16 mm ($\frac{5}{8}$ in.) in	Yield strength of 552 MPa (80 ksi)	Truck frames, brackets, crane booms, rail cars, and other applications

	titanium-aluminum steels		thickness		for which weight savings is important
A 690	High-strength low-alloy steel H-piles and sheet piling	Ni, Cu, Si	Structural-quality H-piles and sheet piling	Corrosion resistance two to three times greater than that of carbon steel in the splash zone of marine structures	Dock walls, sea walls, bulkheads, excavations, and similar structures exposed to seawater
A 709, grade 50 and 50W	Structural steel	V, Nb, N, Cr, Ni, Mo	All structural-shape groups and plate ≤100 mm (4 in.) in thickness	Minimum yield strength of 345 MPa (50 ksi). Grade 50W is a weathering steel.	Bridges
A 714	High-strength low-alloy welded and seamless steel pipe	V, Ni, Cr, Mo, Cu, Nb	Pipe with nominal pipe size diameters of 13 to 660 mm ($\frac{1}{2}$ to 26 in.)	Minimum yield strengths ≤345 MPa (50 ksi) and corrosion resistance two to four times that of carbon steel	Piping
A 715	Steel sheet and strip, hot rolled, high strength low alloy with improved formability	Nb, V, Cr, Mo, N, Si, Ti, Zr, B	Hot rolled sheet and strip	Improved formability ^(c) compared to A 606 and A 607; yield strengths of 345 to 550 MPa (50 to 80 ksi) in four grades	Structural and miscellaneous applications for which high strength, weight savings, improved formability, and good weldability are important
A 808	High-strength low-alloy steel with improved notch toughness	V, Nb	Hot-rolled steel plate ≤ 65 mm ($2\frac{1}{2}$ in.) in thickness	Charpy V-notch impact energies of 40-60 J (30-45 ft · lbf) at -45 °C (-50 °F)	Railway tank cars
A 812	High-strength low-alloy steels	V, Nb	Steel sheet in coil form	Yields strengths of 450-550 MPa (65-85 ksi)	Welded layered pressure vessels
A 841	Plate produced by thermomechanical controlled processes	V, Nb, Cr, Mo, Ni	Plates ≤100 mm (4 in.) in thickness	Yield strengths of 310-345 MPa (45-50 ksi)	Welded pressure vessels
A 847	Cold-formed welded and seamless high-strength low-alloy structural tubing with improved atmospheric-corrosion resistance	Cu, Cr, Ni, Si, V, Ti, Zr, Nb	Welded tubing with maximum periphery of 1625 mm (64 in.) and wall thickness of 16 mm (0.625 in.) or seamless tubing with maximum periphery of 810 mm (32 in.) and wall thickness of 13 mm (0.50 in.)	Minimum yield strengths ≤345 MPa (50 ksi) with atmospheric-corrosion resistance twice that of carbon	Round, square, or specially shaped structural tubing for welded, riveted, or bolted construction of bridges and buildings

A 860	High-strength butt-welding fittings of wrought high-strength low-alloy steel	Cu, Cr, Ni, Mo, V, Nb, Ti	Normalized or quenched and tempered wrought fittings	Minimum yield strengths ≤ 485 MPa (70 ksi)	High-pressure gas and oil transmission lines
A 871	High-strength low-alloy steel with atmospheric corrosion resistance	V, Nb, Ti, Cu, Mo, Cr	As-rolled plate ≤ 35 mm ($1\frac{3}{8}$ in.) in thickness	Atmospheric-corrosion resistance four times that of carbon structural steel	Tubular structures and poles

- (a) For grades and mechanical properties, see Table 16.
- (b) In addition to carbon, manganese, phosphorus, and sulfur. A given grade may contain one or more of the listed elements, but not necessarily all of them; for specified compositional limits, see Table 13.
- (c) Obtained by producing killed steel, made to fine grain practice, and with microalloying elements such as niobium, vanadium, titanium, and zirconium in the composition

Weathering Steels. The first HSLA steels developed were the weathering steels. These steels contain copper and other elements that enhance corrosion resistance, solid-solution strengthening, and some grain refinement of the ferritic microstructure. The solid-solution strengthening effect of several alloying elements is shown in Fig. 9. Of these, copper, phosphorus, and silicon provide corrosion resistance in addition to solid-solution strengthening.

Fig. 9 Solid-solution strengthening of ferrite. Source: Ref 24

Several of the ASTM specifications listed in Table 10 cover weathering steels with enhanced atmospheric-corrosion resistance. The original architectural grade of weathering steel is covered by ASTM A 242, and the heavier structural grade is covered by ASTM A 588. These two steels reduce corrosion by forming their own protective oxide surface film. Although these steels initially corrode at the same rate as plain carbon steel, they soon exhibit a decreasing corrosion rate, and after a few years, continuation of corrosion is practically nonexistent. The protective oxide coating is fine textured, tightly adherent, and a barrier to moisture and oxygen, effectively preventing further corrosion. Plain carbon steel, on the other hand, forms a coarse-textured flaky oxide that does not prevent moisture or oxygen from reaching the underlying noncorroded steel base. Steels conforming to ASTM A 242 and A 588 are not recommended for exposure to highly concentrated industrial fumes or severe marine conditions, nor are they recommended for applications in which they will be buried or submerged. In these environments, the highly protective oxide does not form properly, and corrosion is similar to that for plain carbon steel.

The numerous grades of HSLA weathering steels can be classified into two groups:

- Weathering steels with normal low-phosphorus contents and multiple-alloy additions for solid-solution strengthening and enhanced corrosion resistance
- Proprietary weathering steels with high phosphorus contents (0.05 to 0.15%) for strengthening and corrosion resistance, together with multiple-alloy additions similar to those of the low-phosphorus weathering steels

The atmospheric-corrosion resistance of the low-phosphorus weathering steels (Ref 23) is two to six times that of carbon structural steel, while the proprietary weathering steels may have higher corrosion resistance. For example, an early (circa 1933) proprietary weathering steel, Cor-Ten A produced by United States Steel Corporation, has an atmospheric-corrosion resistance of five to eight times greater than that of carbon steel (Fig. 10), depending on the environment. This high-phosphorus weathering steel has a minimum yield strength of 345 MPa (50 ksi) in section thicknesses up to 13 mm ($\frac{1}{2}$ in.).

Fig. 10 Atmospheric-corrosion resistance of a proprietary high-phosphorus HSLA weathering steel (Cor-Ten A). Composition of weathering steel: 0.12% C (max), 0.20 to 0.50% Mn, 0.07 to 0.15% P, 0.05% S (max), 0.25 to 0.75% Si, 0.25 to 0.75% Cu, 0.30 to 1.25% Cr, and 0.65% Ni (max)

Microalloying with vanadium and/or niobium can improve the yield strength of weathering steels; the addition of niobium also improves toughness. Normalizing or controlled rolling-cooling can also refine the grain size (and thus improve toughness and yield strength). However, if normalizing or accelerated cooling is used to refine grain size, the effect of carbon content and alloy additions on hardenability and the potential for undesirable transformations to upper bainite and Widmanstätten ferrite must be considered.

Microalloyed ferrite-pearlite steels use additions of alloying elements such as niobium and vanadium to increase strength (and thereby increase load-carrying ability) of hot-rolled steel without increasing carbon and/or manganese contents. Extensive studies during the 1960s on the effects of niobium and vanadium on the properties of structural-grade materials resulted in the discovery that very small amounts of niobium and vanadium (<0.10% each) strengthen the standard carbon-manganese steels without interfering with subsequent processing. Carbon content thus could be reduced to improve both weldability and toughness because the strengthening effects of niobium and vanadium compensated for the reduction in strength due to the reduction in carbon content.

The mechanical properties of microalloyed HSLA steels result, however, from more than just the mere presence of microalloying elements. Austenite conditioning, which depends on the complex effects of alloy design and rolling techniques, is also an important factor in the grain refinement of hot-rolled HSLA steels. Grain refinement by austenite conditioning with controlled rolling methods has resulted in improved toughness and high yield strengths in the range of 345 to 620 MPa (50 to 90 ksi) (Ref 25). This development of controlled-rolling processes coupled with alloy design has produced increasing yield strength levels accompanied by a gradual lowering of the carbon content. Many of the proprietary microalloyed HSLA steels have carbon contents as low as 0.06% or even lower, yet are still able to develop yield strengths of 485 MPa (70 ksi). The high yield strength is achieved by the combined effects of fine grain size developed during controlled hot rolling and precipitation strengthening that is due to the presence of vanadium, niobium, and titanium.

The various types of microalloyed ferrite-pearlite steels include:

- Vanadium-microalloyed steels
- Niobium-microalloyed steels
- Niobium-molybdenum steels
- Vanadium-niobium microalloyed steels
- Vanadium-nitrogen microalloyed steels
- Titanium-microalloyed steels
- Niobium-titanium microalloyed steels
- Vanadium-titanium microalloyed steels

These steels may also include other elements for improved corrosion resistance and solid-solution strengthening, or enhanced hardenability (if transformation products other than ferrite-pearlite are desired).

Some specifications of microalloyed HSLA steels do not specify the range of microalloying additions needed to achieve the desired strength level. These steels are often specified in terms of mechanical properties, with the amounts of microalloying elements left to the discretion of the steel producer. For example, SAE specification J410 covers various HSLA steels with varying carbon and manganese limits for sheet, strip, plate, bar, and shapes (Table 11). This specification limits only carbon and manganese contents (besides impurities such as sulfur), with the amounts of microalloying elements depending on the desired mechanical properties and corrosion resistance. Similar specifications based on mechanical properties without specific microalloying amounts also are given in SAE J1392 (hot- and cold-rolled HSLA sheet), SAE J1442 (hot-rolled HSLA plate), and some of the ASTM specifications in Table 10 (ASTM A 242, A 606, and A 715). The other ASTM specifications in Table 10 define specific ranges for microalloying additions.

Table 11 Compositions, mill forms, and characteristics of HSLA steels describe in SAE J410c

See Table 17 for mechanical properties.

Grade(a)	Heat compositional limits, % (b)			Other elements(c)	Available mill forms	Special characteristics
	C (max)	Mn (max)	P (max)			
942X	0.21	1.35	0.04	Nb, V	Plate, bar, and shapes \leq 100 mm (4 in.) in thickness	Similar to 945X and 945C except for better weldability and formability
945A	0.15	1.00	0.04	---	Sheet, strip, plate, bar, and shapes \leq 75 mm (3 in.) in thickness	Excellent weldability, formability, and notch toughness
945C	0.23	1.40	0.04	---	Sheet, strip, plate, bar, and shapes \leq 75 mm (3 in.) in thickness	Similar to 950C except that lower carbon and manganese content improve weldability, formability, and notch toughness
945X	0.22	1.35	0.04	Nb, V	Sheet, strip, plate, bar, and shapes \leq 75 mm (3 in.) in thickness	Similar to 945C except for better weldability and formability
950A	0.15	1.30	0.04	---	Sheet, strip, plate, bar, and shapes \leq 75 mm (3 in.) in thickness	Good weldability, notch toughness, and formability
950B	0.22	1.30	0.04	---	Sheet, strip, plate, bar, and shapes \leq 75 mm (3 in.) in thickness	Fairly good notch toughness and formability
950C	0.25	1.60	0.04	---	Sheet, strip, plate, bar, and shapes \leq 75 mm (3 in.) in thickness	Fair formability and toughness
950D	0.15	1.00	0.15	---	Sheet, strip, plate, bar, and shapes \leq 75 mm (3 in.) in thickness	Good weldability and formability; phosphorus should be considered in conjunction with other elements
950X	0.23	1.35	0.04	Nb, V	Sheet, strip, plate, bar, and shapes \leq 40 mm (1.5 in.) in thickness	Similar to 950C except for better weldability
955X	0.25	1.35	0.04	Nb, V, N	Sheet, strip, plate, bar, and shapes \leq 40 mm (1.5 in.) in thickness	Similar to 945X and 950X except that progressively higher strengths are obtained by increasing the carbon and manganese contents, or by adding nitrogen \leq 0.015%; formability and weldability generally decrease with increased strength; toughness varies with composition and mill practice
960X	0.26	1.45	0.04	Nb, V, N	Sheet, strip, plate, bar, and shapes \leq 40 mm (1.5 in.) in thickness	
965X	0.26	1.45	0.04	Nb, V, N	Sheet, strip, plate, bar, and shapes \leq 20 mm (0.75 in.) in thickness	
970X	0.26	1.65	0.04	Nb, V, N	Sheet, strip, plate, bar, and shapes \leq 20 mm (0.75 in.) in thickness	
980X	0.26	1.65	0.04	Nb, V, N	Sheet, strip, plate, bar, and shapes \leq 10 mm (0.38 in.) in thickness	

(a) Fully killed steel made to fine grain practice may be specified by adding a second suffix, K, for instance, 945XK. Steels made to K practice are normally specified only for applications requiring better toughness at low temperatures than steels made to normal semikilled practice. (b) 0.05% P (max) and 0.90% Si (max), all grades. (c) Elements normally added singly or in combination to produce specified mechanical properties and other characteristics. Other alloying elements such as copper, chromium, and nickel may be added to enhance atmospheric-corrosion resistance.

Vanadium Microalloyed Steels. The development of vanadium-containing steels occurred shortly after the development of weathering steels, and flat-rolled products with up to 0.10% V are widely used in the hot-rolled condition. Vanadium-containing steels are also used in the controlled-rolled, normalized, or quenched and tempered condition.

Vanadium contributes to strengthening by forming fine precipitate particles (5 to 100 nm in diameter) of V(CN) in ferrite during cooling after hot rolling. These vanadium precipitates, which are not as stable as niobium precipitates, are in solution at all normal rolling temperatures and thus are very dependent on the cooling rate for their formation. Niobium precipitates, however, are stable at higher temperatures, which is beneficial for achieving fine-grain ferrite (see the section "Niobium Microalloyed Steels" in this article).

The strengthening from vanadium averages between 5 and 15 MPa (0.7 and 2 ksi) per 0.01 wt% V (Ref 26), depending on carbon content and rate of cooling from hot rolling (and thus section thickness). The cooling rate, which is determined by the hot-rolling temperature and the section thickness, affects the level of precipitation strengthening in a 0.15% V steel, as shown in Fig. 11. An optimum level of precipitation strengthening occurs at a cooling rate of about 170 °C/min (306 °F/min) (Fig. 11). At cooling rates lower than 170 °C/min (306 °F/min), the V(CN) precipitates coarsen and are less effective for strengthening. At higher cooling rates, more V(CN) remains in solution, and thus a smaller fraction of V(CN) particles precipitate and strengthening is reduced. For a given section thickness and cooling medium, cooling rates can be increased or decreased by increasing or decreasing, respectively, the temperature before cooling. Increasing the temperature results in larger austenite grain sizes, while decreasing the temperature makes rolling more difficult.

Fig. 11 Effect of cooling rate on the increase in yield strength due to precipitation strengthening in a 0.15% V steel. Source: Ref 26

Manganese content and ferrite grain size also affect the strengthening of vanadium microalloyed steels. The effect of manganese on a hot-rolled vanadium steel is shown in Table 12. The 0.9% increase in manganese content increased the strength of the matrix by 34 MPa (5 ksi) because of solid-solution strengthening. The precipitation strengthening by vanadium was also enhanced because manganese lowered the austenite-to-ferrite transformation temperature, thereby resulting in a finer precipitate dispersion. This effect of manganese on precipitation strengthening is greater than its effect in niobium steels. However, the absolute strength in a niobium steel with 1.2% Mn is only about 50 MPa (7 ksi) less than that of vanadium steel but at a much lower alloy level (that is, 0.06% Nb versus 0.14% V).

Table 12 Effect of manganese content on the precipitation strengthening of a vanadium-microalloyed steel with a base composition of 0.08% C and 0.30% Si

Vanadium content, %	Yield strength		Change in yield strength	
	MPa	ksi	MPa	ksi
0.3% Mn				
0.00	297	43	0	0
0.08	352	51	55	8
0.14	380	55	83	12
1.2% Mn				
0.00	331	48	0	0

0.08	462	67	131	19
0.14	552	80	221	32

Source: Ref 23, 27

The third factor affecting the strength of vanadium steels is the ferrite grain size produced after cooling from the austenitizing temperature. Finer ferrite grain sizes (which result in not only higher yield strengths but also improved toughness and ductility) can be produced by either lower austenite-to-ferrite transformation temperatures or by the formation of finer austenite grain sizes prior to transformation. Lowering the transformation temperature, which affects the level of precipitation strengthening as mentioned above, can be achieved by alloy additions and/or increased cooling rates. For a given cooling rate, further refinement of ferrite grain size is achieved by the refinement of the austenite grain size during rolling.

The austenite grain size of hot-rolled steels is determined by the recrystallization and grain growth of austenite during rolling. Vanadium hot-rolled steels usually undergo conventional rolling but are also produced by recrystallization controlled rolling (see the section "Controlled Rolling" in this article). With conventional rolling, vanadium steels provide moderate precipitation strengthening and relatively little strengthening from grain refinement. The maximum yield strength of conventionally hot-rolled vanadium steels with 0.25% C and 0.08% V is about 450 MPa (65 ksi). The practical limit of yield strengths for hot-rolled vanadium-microalloyed steel is about 415 MPa (60 ksi), even when controlled rolling techniques are used. Vanadium steels subjected to recrystallization controlled rolling require a titanium addition so that a fine precipitate of TiN is formed that restricts austenite grain growth after recrystallization. Yield strengths from conventional controlled rolling are limited to a practical limit of about 415 MPa (60 ksi) because of the lack of retardation of recrystallization. When both strength and impact toughness are important factors, controlled-rolled low-carbon niobium steel (such as X-60 hydrogen-induced cracking resistant plate) is preferable.

Niobium Microalloyed Steels. Like vanadium, niobium increases yield strength by precipitation hardening; the magnitude of the increase depends on the size and amount of precipitated niobium carbides (Fig. 12). However, niobium is also a more effective grain refiner than vanadium. Thus, the combined effect of precipitation strengthening and ferrite grain refinement makes niobium a more effective strengthening agent than vanadium. The usual niobium addition is 0.02 to 0.04%, which is about one-third the optimum vanadium addition.

Fig. 12 Effect of niobium carbide on yield strength for various sizes of niobium carbide particles

Strengthening by niobium is 35 to 40 MPa (5 to 6 ksi) per 0.01% addition. This strengthening was accompanied by a considerable impairment of notch toughness until special rolling procedures were developed and carbon contents were lowered to avoid formation of upper bainite. In general, high finishing temperatures and light deformation passes should be avoided with niobium steels because that may result in mixed grain sizes or Widmanstätten ferrite, which impair toughness.

Niobium steels are produced by controlled rolling, recrystallization controlled rolling, accelerating cooling, and direct quenching. The recrystallization controlled rolling of niobium steel can be effective without titanium, while recrystallization rolling of vanadium steels requires titanium for grain refinement. Also, much less niobium is needed, and niobium-titanium steels can be recrystallization controlled rolled at higher temperatures. At present, offshore platform steels up to 75 mm (3 in.) thick with yield strengths of 345 to 415 MPa (50 to 60 ksi) are routinely produced.

Vanadium-Niobium Microalloyed Steels. Steels microalloyed with both niobium and vanadium provide a higher yield strength in the conventionally hot-rolled condition than that achievable with either element alone. As conventionally hot rolled, the niobium-vanadium steels derive almost all of their increased strength from precipitation strengthening and therefore have high ductile-brittle transition temperatures. If the steel is controlled rolled, the addition of both niobium and vanadium together is especially advantageous for increasing the yield strength and lowering ductile-brittle transition temperatures by grain refinement.

Usually niobium-vanadium steels are made with relatively low carbon contents (<0.10% C). This reduces the amount of pearlite and improves toughness, ductility, and weldability. These steels are frequently referred to as pearlite-reduced steels.

Niobium-molybdenum microalloyed steels may have either a ferrite-pearlite microstructure or an acicular ferrite microstructure. Steels with the latter microstructure are discussed in the section "Acicular Ferrite (Low-Carbon Bainite) Steels" in this article.

In ferrite-pearlite niobium steels, the addition of molybdenum increases the yield strength and tensile strength by about 20 MPa (3 ksi) and 30 MPa (4.5 ksi), respectively, per 0.1% Mo, over an investigated range of 0% to 0.27% Mo (Ref 28).

The principal effect of molybdenum on the microstructure is to alter the morphology of the pearlite and to introduce upper bainite as a partial replacement for pearlite. However, because the individual strength values of pearlite and bainite are somewhat similar, it has been proposed that the strength increase is due to solid-solution strengthening and enhanced Nb(CN) precipitation strengthening caused by a molybdenum-niobium synergism. The interaction between molybdenum and niobium (or vanadium) has been proposed as an explanation for the increase in precipitation strengthening by the addition of molybdenum. This effect has been attributed to the reduced precipitation in austenite from an increase in solubility arising from a decrease in carbon activity brought about by molybdenum (Ref 28). With less precipitation in austenite, more precipitates could form in the ferrite, resulting in enhanced strength. Also, molybdenum has been identified in the precipitates themselves; its presence may increase their strengthening effectiveness by increasing coherency strains and/or by increasing the volume fraction of precipitation (Ref 28). These metallurgical factors, when considered in conjunction with the effectiveness of controlled rolling to temperatures just below the A_{r3} temperature, have led to the development of a more economical X-70 molybdenum-niobium linepipe steel (Ref 28).

Vanadium-Nitrogen Microalloyed Steels. Vanadium combines more strongly with nitrogen than does niobium and forms VN precipitates in vanadium-nitrogen steel. Nitrogen additions to high-strength steels containing vanadium have become commercially important because the additions enhance precipitation hardening. Precipitation hardening may be accompanied by a drop in notch toughness, but this can often be overcome by lowering the carbon content. The precipitation of vanadium nitride also acts as a grain refiner.

Some producers use nitrogen additions to assist in the precipitation strengthening of controlled-cooled sheet and plate with thicknesses above 9.5 mm (0.375 in.). In one case (Ref 23), hot-rolled plates with vanadium and 0.018 to 0.022% N have been produced by controlled cooling in thicknesses up to 16 mm (0.625 in.) with yield strengths of 550 MPa (80 ksi). However, delayed cracking is a major problem in these steels. The use of nitrogen is not recommended for steels that will be welded because of its detrimental effect on notch toughness in the heat-affected zone.

Titanium-Microalloyed Steels. Titanium in low-carbon steels forms into a number of compounds that provide grain refinement, precipitation strengthening, and sulfide shape control. However, because titanium is also a strong deoxidizer, titanium can be used only in fully killed (aluminum deoxidized) steels so that titanium is available for forming into compounds other than titanium oxide. Commercially, steels precipitation strengthened with titanium are produced in thicknesses up to 9.5 mm (0.375 in.) in the minimum yield strength range from 345 to 550 MPa (50 to 80 ksi), with controlled rolling required to maximize strengthening and improve toughness.

Like niobium and/or vanadium steels, titanium microalloyed steels are strengthened by mechanisms that involve a combination of grain refinement and precipitation strengthening; the combination depends on the amount of alloy additions and processing methods. In reheated or continuously cast steels, small amounts of titanium ($\leq 0.025\%$ Ti) are effective grain refiners because austenite grain growth is retarded (Fig. 13(a)) by titanium nitride. Small amounts of titanium are also effective in recrystallization controlled rolling because titanium nitride retards the grain growth of recrystallized austenite. In conventional controlled rolling, however, titanium is a moderate grain refiner, causing less refinement than niobium but more than vanadium.

Fig. 13(a) Austenite grain coarsening during reheating and after hot rolling for a holding time of 30 min. Titanium contents were between 0.008 and 0.022% Ti. Source: Ref 25

In terms of precipitation strengthening (Fig. 13(b)), a sufficient amount of titanium is required to form titanium carbide. Small percentages of titanium ($<0.025\%$ Ti) form mainly into TiN , which has an effect on austenite grain growth but little effect on precipitation strengthening because the precipitates formed in the liquid are too coarse. Increasing the titanium content leads to the formation first of titanium-containing manganese sulfide inclusions $(\text{Mn, Ti})\text{S}$, and then of globular carbosulfides, $\text{Ti}_4\text{C}_2\text{S}_2$ (which provide sulfide shape control). The formation of $\text{Ti}_4\text{C}_2\text{S}_2$ is accompanied by and followed by titanium carbide (TiC) formation, which can be used for the precipitation strengthening of low-carbon steels. To determine the amount of titanium that is available for precipitation strengthening, the total titanium content must be adjusted for the formation of the coarse, insoluble titanium nitride and carbosulfides that do not participate in precipitation strengthening.

Fig. 13(b) The dependence of precipitation strengthening on average precipitate size (\bar{x}) and fraction according to theory and experimental observations for given microalloying additions. Source: Ref 22

Experimentally observed strength increases from TiC precipitation have ranged up to 440 MPa (64 ksi) for very fine particles (less than 30 Å) and a relatively large fraction of precipitate (Fig. 13(b)). If sufficient amounts of titanium are used, titanium carbide can provide more precipitation strengthening than either niobium or vanadium. However, because higher levels of precipitation strengthening are generally associated with reduced toughness, grain refinement would be necessary to improve toughness. Titanium is a moderate grain refiner (compared to niobium and vanadium in hot-rolled steels), and the high levels of precipitation strengthening of titanium microalloyed steels result in a severe penalty in toughness. Using only titanium as a strengthener in high-strength hot-rolled strip has also resulted in unacceptable variability in mechanical properties (see the paper "Restricted Yield Strength Variation in High Strength Low Alloy Steels" by E.G. Hamburg in Ref 11).

Titanium-Niobium Microalloyed Steels. Although precipitation-strengthened titanium steels have limitations in terms of toughness and variability of mechanical properties, research has shown that an addition of titanium to low-carbon niobium steels results in an overall improvement in properties (see, for example, the article "Recent Developments in Automotive Hot-Rolled Strip Steels" by G. Tither in Ref 25). Titanium increases the efficiency of niobium because it combines with the nitrogen-forming titanium nitrides, thus preventing the formation of niobium nitrides. This allows for increased solubility of niobium in the austenite resulting in subsequent increased precipitation of Nb(C,N) particles in the ferrite. The addition of 0.04% titanium to steel strip containing various amounts of niobium consistently produced a yield strength increase of about 105 MPa (15 ksi) for a coiling temperature of 675 °C (1250 °F). Hot-rolled niobium-titanium steel strip is effective in achieving yield strengths of 550 MPa (80 ksi) in ferrite-pearlite steels. An addition of either vanadium or molybdenum can raise yield strengths to 690 MPa (100 ksi).

As-rolled pearlitic structural steels are a specific group of steels in which enhanced mechanical properties (and, in some cases, resistance to atmospheric corrosion) are obtained by the addition of moderate amounts of one or more alloying elements other than carbon. Some of these steels are carbon-manganese steels and differ from ordinary carbon steels only in having a greater manganese content. Other pearlitic structural steels contain small amounts of alloying elements, which are added to enhance weldability, formability, toughness, and strength.

The as-rolled pearlitic structural steels are characterized by as-rolled yield strengths in the range of 290 to 345 MPa (42 to 50 ksi). They are not intended for quenching and tempering and should not be subjected to such treatment. For certain applications, they may be annealed, normalized, or stress relieved, processes which may alter mechanical properties.

When these steels are used in welded structures, care must be exercised in grade selection and in the specification of the welding process details. Certain grades may be welded without preheating or postheating. The basic disadvantages of these steels is that the pearlitic microstructure raises the ductile-brittle transition temperature but does not improve yield strengths. In addition, the high carbon content (relative to other HSLA steels) reduces weldability.

Acicular Ferrite (Low-Carbon Bainite) Steels. Another approach to the development of HSLA steels is to obtain a very fine, high-strength acicular ferrite microstructure, instead of the usual polygonal ferrite microstructure, during the cooling transformation of ultralow carbon (<0.08% C) steels with sufficient hardenability (by additions of manganese, molybdenum, and/or boron). Niobium can also be used for precipitation strengthening and grain refinement. The principal difference between the structure of acicular ferrite (which is also referred to as low-carbon bainite) and that of polygonal ferrite is that the former is characterized by a high dislocation density and fine, highly elongated grains that are not exhibited in polygonal ferrite.

Acicular ferrite steels can be obtained by quenching or, preferably, by air cooling with suitable alloys for hardenability. The principal advantage of this type of HSLA steel is the unusual combination of high yield strengths (415 to 690 MPa, or 60 to 100 ksi), high toughness (Fig. 14), and good weldability. A major application of these steels is linepipe in arctic conditions.

Fig. 14 Impact toughness and yield strengths of 25 mm (1 in.) thick, controlled-rolled, ultralow-carbon bainitic steel plate. In addition to the molybdenum contents shown, nominal contents of other alloying elements included 0.024 to 0.027% C, 0.92 to 1.00% Mn, 3.54 to 3.63% Ni, and 0.050 to 0.055% Nb. Source: Ref 29

Typical properties of conventionally rolled, air-cooled 13 mm (0.5 in.) plate are (Ref 24):

- Yield strength: 470 to 530 MPa (68 to 77 ksi)
- Charpy V-notch 50% shear area fracture appearance transition temperature: -23 to 10 °C (-10 to 50 °F)
- Charpy V-notch ductile-shelf energy: greater than 136 J (100 ft · lbf)

Properties of a controlled-rolled acicular ferrite steel are summarized in Fig. 14.

The major application of acicular ferrite steel involves oil pipelines in arctic conditions. This application requires a combination of high strength, superior toughness, excellent resistance to hydrogen-induced cracking, and first-rate field weldability. In answer to these needs, Nippon Kokan K.K. developed a tough acicular ferrite steel for linepipe through the optimization of carbon and niobium content, the addition of boron, and/or the application of on-line accelerated cooling.

In this pipe, optimum carbon content ranges from 0.01 to 0.05%. Below 0.01% carbon, grain boundaries in the heat-affected zone (HAZ) are embrittled, resulting in intergranular, hydrogen-induced cracking and loss of toughness in the HAZ. The addition of boron and/or the application of on-line accelerated cooling ensures both high strength and superior toughness, along with desirable welding properties.

Three grades for arctic service are available: X-65, X-70, and X-80. An X-70 composition includes 0.03% C, 0.25% Si, 1.91% Mn, 0.008% P, 0.001% S, 0.048% N, plus titanium, boron, and calcium. Work at Bethlehem Steel Corporation to improve the properties of X-70 linepipe through the optimization of composition and processing parameters found that:

- An X-70 strength requirement, along with a 68 J (50 ft · lbf) minimum Charpy energy at 0 °C (32 °F) can be met with a controlled-rolled, low-carbon, low-sulfur vanadium-niobium composition. Full-curve Charpy data for the 10.9 mm (0.429 in.) wall linepipe indicate that with the chemistry and processing used, a 68 J (50 ft · lbf) Charpy requirement could also be met at -18 °C (0 °F) at this wall thickness
- There is a positive shift in both yield and tensile strength during pipe forming that is related to the amount of expansion and the corresponding stress-strain characteristics, such as work hardening and Lüders extension. As the percentage of expansion increases, the shift in yield strength rises continuously, but the shift in tensile strength levels off at about 27 to 35 MPa (4 to 5 ksi) after about 1.4% expansion
- Various Linde wire and flux combinations produce excellent toughness in the pipe body and HAZ, but only the Linde wire 83 and Linde flux 101 combinations provide excellent Charpy absorbed energies in the weld metal, such that the pipe body, heat-affected zone, and weld metal satisfy a 68 J (50 ft · lbf) requirement at 0 °C (32 °F)

Dual-phase steels have a microstructure with 80 to 90% polygonal ferrite and 10 to 20% martensite islands dispersed throughout the ferrite matrix. These steels have a low yield strength and continuous yielding behavior; therefore they form just like low-strength steel, but they can also provide high strength in the finished component because of their rapid work-hardening rate. Figure 8 compares the ductility and tensile strength of dual-phase steels with other HSLA steels. Typical as-shipped yield strength is 310 to 345 MPa (45 to 50 ksi).

Dual-phase steels can be produced from low-carbon steels in three ways (Ref 30):

- Intercritical austenitization of carbon-manganese steels followed by rapid cooling
- Hot rolling with ferrite formers such as silicon and transformation-delaying elements such as chromium, manganese, and/or molybdenum
- Continuous annealing of cold-rolled carbon-manganese steel followed by quenching and tempering

Additional information on dual-phase steels is contained in the article "Dual-Phase Steels" in this Volume.

Interstitial-Free (IF) Steels. Steels with very low interstitial contents exhibit excellent formability with low yield strength, high elongation, and good deep drawability (Fig. 8c). With the addition of carbonitride-forming elements, the deep drawability and the non-aging properties are further improved. The effect of niobium, unlike that of other microalloyed elements, is to improve the planar anisotropy, reducing earing. This is due to the finer grain size already in the hot strip material prior to cold rolling. Titanium is also added to improve the effectiveness of niobium (see the section "Titanium-Niobium Microalloyed Steels" in this article). Information on the processing and steelmaking of IF steels is given in the articles "Steel Processing Technology" and "Microstructures, Processing, and Properties of Steels" in this Volume.

Inclusion Shape Controlled Grades. An important development in microalloyed HSLA steels is the use of inclusion shape control. Sulfide inclusions, which are plastic at rolling temperatures and thus elongate and flatten during rolling, adversely affect ductility in the short transverse (through thickness) direction. The main objective of inclusion shape control is to produce sulfide inclusions with negligible plasticity at even the highest rolling temperatures.

The preferred method for sulfide shape control involves calcium-silicon ladle additions. However, sulfide shape control is also performed with small additions of rare-earth elements, zirconium, or titanium that change the shape of the sulfide inclusions from elongated stringers to small, dispersed, almost spherical globules. This change in the shape of sulfide inclusions substantially increases transverse impact energy and improves formability. Inclusion shape control was introduced with the advent of hot-rolled sheet and light plate having a yield strength of 550 MPa (80 ksi) in the as-rolled condition. This technology has also been extended to include grades with lower yield strengths ranging from 310 to 550

MPa (45 to 80 ksi). The improved formability of these grades is recognized in ASTM A 715. Inclusion shape control with rare-earth elements is seldom used because rare-earth elements produce relatively dirty steel.

Sulfide inclusion shape control performs several important roles in HSLA steels. It improves transverse impact energy, and it can minimize lamellar tearing in welded structures by improving through-thickness properties that are critical in constrained weldments.

Control of HSLA Steel Properties

Most HSLA steels are furnished in the as-hot-rolled condition with ferritic-pearlitic microstructure. The exceptions are the controlled-rolled steels with an acicular ferrite microstructure and the dual-phase steels with martensite dispersed in a matrix of polygonal ferrite. These two types of HSLA steels use the formation of eutectoid structures for strengthening, while the ferritic-pearlitic HSLA steels generally require strengthening of the ferrite. Pearlite is generally an undesirable strengthening agent in structural steels because it reduces impact toughness and requires higher carbon contents. Moreover, yield strength is largely unaffected by a higher pearlite content.

Strengthening Mechanisms in Ferrite. The ferrite in HSLA steels is typically strengthened by grain refinement, precipitation hardening, and, to a lesser extent, solid-solution strengthening. Grain refinement is the most desirable strengthening mechanism because it improves not only strength but also toughness.

Grain refinement is influenced by the complex effects of alloy design and processing methods. For example, the various methods of grain refinement used in the three different stages of hot rolling (that is, reheating, hot rolling, and cooling) include:

- The addition of titanium (Fig. 13(a)) or aluminum to retard austenite grain growth when the steel is reheated for hot deformation or subsequent heat treatment
- The controlled rolling of microalloyed steels to condition the austenite so that it transforms into fine-grain ferrite
- The use of alloy additions and/or faster cooling rates to lower the austenite-to-ferrite transformation temperature

The use of higher cooling rates for grain refinement may require consideration of its effect on precipitation strengthening and the possibility of undesirable transformation products.

Precipitation strengthening occurs from the formation of finely dispersed carbonitrides developed during heating and cooling. Because precipitation strengthening is generally associated with a reduction in toughness, grain refinement is often used in conjunction with precipitation strengthening to improve toughness.

Precipitation strengthening is influenced by the type of carbonitride, its grain size, and, of course, the number of carbonitrides precipitated. The formation of MC is the most effective metal carbide in the precipitation strengthening of microalloyed niobium, vanadium, and/or titanium steels. The number of fine MC particles formed during heating and cooling depends on the solubility of the carbides in austenite and on cooling rates (Fig. 11). Figure 13(b) shows the dependence of precipitation strengthening on precipitate size and volume fraction.

Steelmaking. Precise steelmaking operations are also essential in controlling the properties and chemistry of HSLA steels. Optimum property levels depend on such factors as the control of significant alloying elements and the reduction of impurities and nonmetallic inclusions.

Developments in secondary steelmaking such as desulfurization, vacuum degassing, and argon shrouding have enabled better control of steel chemistry and the effective use of microalloyed elements. In particular, the use of vacuum degassing equipment allows the production of interstitial-free (IF) steels. The IF steels exhibit excellent formability, high elongation, and good deep drawability (Fig. 8).

Compositions and Alloying Elements. Chemical compositions for the HSLA steels specified by ASTM standards (Table 10) are listed in Table 13. The principal function of alloying elements in these ferrite-pearlite HSLA steels, other than corrosion resistance, is strengthening of the ferrite by grain refinement, precipitation strengthening, and solid-

solution strengthening. Solid-solution strengthening is closely related to alloy contents (Fig. 9), while grain refinement and precipitation strengthening depend on the complex effects of alloy design and thermomechanical treatment.

Table 13 Compositional limits for HSLA steel grades described in ASTM specifications

(a) For characteristics and intended uses, see Table 10; for mechanical properties, see Table 16.

(b) If a single value is shown, it is a maximum unless otherwise stated.

(c) Values may vary, or minimum value may exist, depending on product size and mill form.

- (d) Optional or when specified.
- (e) May be purchased as type 1 (0.005-0.05 Nb), type 2 (0.01-0.15 V), type 3 (0.05 Nb, max, plus 0.02-0.15 V) or type 4 (0.015 N, max, plus V \geq 4 N).
- (f) If chromium and silicon are each 0.50% min, the copper minimum does not apply.
- (g) May be substituted for all or part of V.
- (h) Niobium plus vanadium, 0.02 to 0.15%.
- (i) Nitrogen with vanadium content of 0.015% (max) with a minimum vanadium-to-nitrogen ratio of 4:1.
